## Transcriptome characterisation of the intra-mammalian stage of male and female Schistosoma mansoni

Andreas Florian Sessler<br>Darwin College<br>University of Cambridge

This dissertation is submitted for the degree of Doctor of Philosophy

October 2017

## Declaration

This dissertation is the result of my own work - all work done in collaboration being clearly references in the text. The work presented here was performed at the Wellcome Trust Sanger Institute (Hinxton). None of the work has been submitted, or, is being concurrently submitted for a degree or diploma or other qualification at the University of Cambridge or any other University. This thesis does not exceed the word limit established by the Biology Degree Committee.

## Acknowledgements

During my time at the Sanger Institute I had the fortune of being helped and advised by many people. First I'd like to thank my supervisor Matt (Dr. Matt Berriman) for his support and guidance over the last few years. This worm would not have been possible without him. I also want to thank all of Team 133 for their great help and friendship. In particular Anna (Dr. Anna Protasio) for sharing her knowledge and experience in all things "Schisto" with me, Lia (Dr. Lia Chappell) and Hayley (Dr. Hayley Bennett) for all their help in the laboratory as well as Adam (Dr. Adam Reid) for sharing his bioinformatics skills with me.

Furthermore I would like to thank several other people at the Sanger Institute, including the pathogen informatics team for their constant support. I also want to thank Dr. Simon Clare and Cordelia Brandt for their help with the infections and perfusions and Dave Goulding for his help with electron microscopy. Next, I would also like to thank Prof. Dr. Christoph Grevelding, Dr. Thomas Quack and Dr Zhigang Liu from the Institut für Parasitologie - Justus-Liebig-Universität Gießen for the productive collaboration, the results of which form part of this thesis. I also want to thank Prof. Andrew MacDonald and Prof. Mike Doenhoff for providing schistosome material at many points during my work as well as Dr Peter Olson for hosting me at the Natural History Museum to learn about in situ hybridisation.

Finally I would like to Aki MacFarlane and my family for their continuous support throughout my work at the Sanger Institute.

## Summary

Schistosoma mansoni is a member of a genus of platyhelminths whose members cause the disease schistosomiasis. Particularly prevalent in sub-Saharan Africa, it is thought to be directly responsible for approximately 5500 deaths per year, as well as contributing significantly to morbidity, being responsible for 3.3 million lost disability-adjusted life years. Schistosomes are dioecious and male and female worms find one another and pair in the blood vessels of the host's liver. This sets in motion a unique feature of schistosome biology, the pairingdependent sexual maturation of the female worms. Over the course of the next three weeks, the females fully develop their reproductive organs, especially ovaries and vitellarian tissue, to allow for the production of large quantities of eggs, which not only play a crucial role in the transmission of the parasites, but are also responsible for much of the pathology associated with schistosomiasis.

This thesis aims to explore the changes in gene expression which take place following pairing, and result in the sexual maturation of females. To do so, RNASeq data was produced from male and female worms from mixed sex as well as single sex infections at $18,21,28,35,38$ and 49 days post infection and analysed to understand when and how gene expression changes in paired worms. Then gene expression was examined in worms that had been removed from their partner to examine the process of regression, where female worms lose much of their reproductive tissue. The last experiments describe examine gene expression in the testes and ovaries of schistosomes, to reveal differences between the gonads of worms from mixed and single sex infections and understand in more detail how these worms may regulate the growth of their reproductive organs, contributing to our knowledge of schistosome biology.

Chapter 1

## Introduction

### 1.1 Introduction

Schistosomiasis is caused by a genus of platyhelminths called Schistosoma; an estimated 200 million people require treatment for the disease annually, approximately $90 \%$ of whom live in sub-Saharan Africa (WHO, 2018). According to the Global Burden of Disease Study the death of 5500 people was directly caused by schistosomiasis in 2013 (Naghavi et al., 2015). However the precise number is difficult to estimate because of the difficulties of measuring the contribution of chronic schistosomiasis to conditions such as kidney failure and bladder cancer and estimates are as high as 200,000 deaths per year globally WHO (2018).

### 1.2 Biology of schistosomes

Schistosoma mansoni as well as several other species of schistosomes, notably $S$. japonicum and Schistosoma hematobium, are responsible for schistosomiasis. Schistosomes belong to the class Trematoda, which usually have a flattened, oval body shape ranging in length from around 0.1 cm to 7 cm with a ventral as well as an oral sucker (Barnes and Robert, 1982). Schistosomes are around 0.6-1.1 cm long and 0.1 cm wide, with a long, slim body (Machado-Silva et al., 1997). The morphology of male and female worms differs considerably (Loker \& Brant, 2006). Male worms maintain the typical flattened body shape of trematodes but curled up to form the gynecophoral canal, whereas the female worms have a cylindrical profile (Figure 1.1).

Figure 1.1: Scanning electron microscopy of adult Schistosoma mansoni couples. After pairing, the female worm resides inside the gynecophoral canal (GC) of the male. Both worms have an oral (OS) as well as a ventral sucker (VS). The tegument of male worms is covered with tegumental tubercles (TT). These images were taken in collaboration with Dave Goulding, WTSI, Hinxton.

### 1.2.1 Life cycle

The $S$. mansoni life cycle (see Figure 1.2) is similar to that of other trematodes and involves a mollusc and a mammalian host (Tucker et al., 2013). However, unlike most trematodes, the members of the Schistosomatidae, the family $S$. mansoni belongs to, are dioecious (Loker \& Brant, 2006). This means that there are distinct male and female worms instead of hermaphrodites. The life cycle of S. mansoni features two hosts, a molluscan intermediate host, in which the parasites undergo asexual reproduction, and the vertebrate definitive host, in which the adult worms reproduce sexually and lay eggs (Tucker et al., 2013). When the eggs are placed in fresh water, ciliated larvae called miracidia (136 $\pm 3$ $\mu \mathrm{m}$ in length and $54 \pm 1 \mu \mathrm{~m}$ in width (Eklu-Natey et al., 1985) are released. $S$. mansoni miracidia invade the intermediate host - fresh water snails of the genus Biomphalaria - by burrowing through the skin of its foot (Cosseau et al., 2009). Inside the snail, the miracidia develop into primary (or mother) sporocysts,
which in turn produce secondary (or daughter) sporocycsts by asexual reproduction (Cosseau et al., 2009).

Figure 1.2: Life cycle of Schistosoma species. 1) Eggs are excreted via faeces or in the case of S. haematobium in the urine and reach fresh water. 2) Miracidia hatch from the eggs and seek a snail host. 3) The miracidia penetrate a snail host (in the case of S. mansoni a snail of the genus Biomphalaria) and 4) two generations of sporocysts develop from the miracidia inside the host. 5) Cercariae are produced and released into the water. 6) Cercariae penetrate the human skin, 7) shedding their tail and transforming into schistosomulae. 8) After moving through the circulation and lungs for several weeks, 9) male and female adult worms pair in the liver and 10) relocate to the mesenteric system of the bowel (or the venous plexus of the bladder in the case of S. haematobium). The couples then start egg-laying, thereby continuing the life cycle. Reproduced from CDC (2012);
https://www.cdc.gov/parasites/schistosomiasis/biology.html

Each daughter sporocyst produces a clonal population of cercariae, the life cycle stage infecting humans (McKerrow \& Salter, 2002). By shedding during daylight hours, S. mansoni maximise the chances of the cercariae being released when a suitable mammalian host might be nearby (Fingerut et al., 2003). The cercariae use their forked tail for locomotion and use changes in light and the presence of medium-chain fatty acids in the skin to detect a host (McKerrow \& Salter, 2002). When a cercaria comes into contact with a suitable host, it attaches to the skin and uses proteases to break into the skin, migrating into the subcutaneous tissue, losing its tail in the process (Salter et al., 2000).

Following host invasion, the parasites transform into schistosomules. They spend around days traveling through the skin and circulation, migrate through the lungs (peaking here around 5-6 d.p.i.), then continuing over the course of the next two weeks until they enter the portal vessel of the liver (P. Miller \& Wilson, 1980). There, they begin to feed on blood as the gut develops and they begin to grow. At this stage the male worms become visibly larger than the females (Basch, 1991) From around 21 day post infection (d.p.i.) onward the parasites mature and males and females commence pairing around 28 d.p.i. Basch, 1991). It is well established that female worms require pairing with a male partner to develop mature gonads and vitellaria to become sexually mature (Kunz, 2001). Without pairing, female worms remain stunted and infertile (Collins \& Newmark, 2013). Around 35 d.p.i., S. mansoni pairs have usually migrated into the mesenteric blood vessels and maturing females produce the first eggs (Basch, 1991). However, there is considerable variation in the time it takes worms to migrate through different parts of their hosts' bodies, depending on the species
of worm in question as well as the host species - mice, rats, hamsters and humans - varying by as much as 20 days (Yolles et al., 1949; Wilson, 1978; Crabtree \& Wilson, 1986; Miller \& Wilson, 1980).

After $S$. mansoni pairs have migrated to the mesentery and commenced egg production, they will often continue to produce eggs for years if left untreated (Harris et al., 1984) Approximately half of the eggs get trapped in various organs (LoVerde et al., 2005), where they cause considerable damage (see Chapter 1.3.2). The remaining eggs cross through the wall of the intestine into the lumen of the gut from where they are excreted with faeces (deWalick et al., 2011) If eggs wash into fresh water, miracidia hatch, ready to invade the snail intermediate host, and the cycle repeats.

Aside from the migration through the host, another critical aspect of worm development is the morphological changes that take place during the first 6-7 weeks after infection. Cort (1921) describes the development of male and female schistosomes from mixed sex (MS) infections beginning at the lung stage (around 7 d.p.i) until the worms have matured fully and commence oviposition (around 35 d.p.i.). The author notes that at 7 d.p.i. the young worms remain at approximately the same size as schistosomules with the gut starting to develop. The first differences between male and female worms are described at 15 d.p.i., when the worms reach the portal vessel of the liver, commence feeding on blood and begin to grow. Males are larger and have more developed oral and ventral suckers at this time. At around 21 d.p.i. organogeny begins: male worms develop testes and in females a uterus becomes visible. After another week of maturation,
at around 28 d.p.i., gametogeny is thought to take place. Males have been shown to possess 8 testes at 28 d.p.i., some of which contain sperm, and females to have developed ovaries. At 28 d.p.i., Cort (1921) first observed pairing of worms, but also showed that maturation of the vitellarium in particular requires a further week. At 30 d.p.i., the author demonstrated the presence of vitelline globes, but found that oviposition generally begins to occur at 35 d.p.i. At this point, females have well-developed vitelline glands to provide a steady supply of egg shell proteins, whilst male worms produce large quantities of sperm for fertilisation. Very similar observations were made by Biolchini et al. (2006), but technological improvements over the 85 years that separated these two studies, most notably confocal microscopy, allowed them to study the development of the worm organs in more detail. Indeed the latter authors noticed that at week three 4759\% of males had developed the gynecophoral canal, $5 \%$ of females had developed an ootype, and 33\% of females had developed ovaries, whereas Cort (1921) did not observe ovaries at this time and made no mention of the gynecophoral canal development. At week four, Biolchini et al. (2006) found that 15-26\% of male worms began to develop tegumental tubercles (Figure 1.1). Also, $69 \%$ of females were found to have ovaries and 12-75\% an ootype, with a single female presenting with a fertilised egg. In addition, Biolchini et al. (2006) found the oral suckers of male worms to be significantly larger in size than that of females at 21-28 d.p.i., an important difference at 21 d.p.i. for distinguishing worms morphologically. Both papers noted the significance of pairing in the development of the females, which, unlike male worms, do not mature sexually until paired. In particular, development of the vitellarium and maturation of the ovaries was observed only following pairing (Biolchini et al., 2006; Cort, 1921).

Notably, the development of S. japonicum appears to occur at a slightly faster pace, as most worms were found to be paired by 22 d.p.i. and the first sperm and mature oocytes are first observed at the same time, presumably in worms that paired particularly early, and sexually mature worms are found at 28 d.p.i. (Wang et al., 2017).

The induced maturation of the reproductive organs of a paired female worm culminates in the production of eggs. The function of the ovary is to produce viable, fertilised oocytes, the vitellarium, on the other hand, produces eggshell precursor proteins and provides nutrient reserves for the developing embryo in the form of lipid droplets (LoVerde et al., 2005). After oocytes have become fertilised with the male sperm inside the female oviduct, the fertilised cells move to the vitello-oviduct, where they are surrounded by approximately 38 vitellocytes (Loverde \& Chen, 1991) (Figure 1.3). The maturation of vitellocytes is commonly divided into four stages (Erasmus, 1975): The first is a stem cell stage of undifferentiated, small cells near the periphery of the vitelline lobes (S1). Then the cell begins to differentiate and grow in size (S2). The cells then begin to synthesise large amounts of proteins and form vitelline droplets; while the rate of protein synthesis increases the vitelline droplets begin to form clusters. Subsequently, lipid droplets and a small number of $\beta$-glycogen particles accumulate to provide energy to the embryo (S3). The final stages of development, mature vitellocytes (S4), leave through the vitelline duct to reach the ootype (Figure 1.3) (Wang \& Collins, 2016). Approximately 11,000 S4 vitellocytes are produced daily by mature females (LoVerde et al., 2005) and to
satisfy this demand the vitellarium takes up a large portion of the female worm's body (Galanti et al., 2012).

Figure 1.3: Diagram of the female reproductive organs, reproduced from Wang \& Collins (2016). Left: The relative positions are shown for the gonopore, ootype, Mehlis' gland, oviduct, vitelline duct, ovary, vitellaria and seminal receptacle. Rigth: vitellocytes move towards the central vitelline duct as they mature through a sequence of stages (S1-S4); stem cell-like S1 cells, proliferating S2 cells, larger S3 vitellocytes accumulating granules, and finally mature S4 vitellocytes.

Each paired female has been estimated to lay around 300 eggs per day for several years (Loverde \& Chen, 1991). Schistosome are estimated to live for 2.74.5 years ( 3.3 on average) (Goddard \& Jordan, 1980) although there are reports of worms surviving and continuing to produce viable eggs for up to 47 years (Harris et al., 1984; Markel et al., 1978; Warren et al., 1974). Adult S. mansoni cannot reproduce asexually and female reproductive maturity is critically dependent on pairing with a male worm. Not only does transmission rely on
efficient egg production but also the pathology caused by schistosomes is in large parts driven by the host immune reaction against the eggs of these parasites and the resulting inflammation and formation of granulomas in the liver and spleen (Gryseels et al., 2006). For these reasons, the process of pairing-induced maturation is an attractive target for intervention and an intensely studied aspect of schistosome biology (Loverde \& Chen, 1991).

### 1.3 Impact on human welfare

According to the WHO (2018) Approximately 200 million people required treatment for schistosomiasis in 2016, of which only about 90 million receive it. Furthermore the WHO (2018) estimates that approximately $90 \%$ of those infected live in Africa, with limited access to medical care. Hence the number of schistosomiasis-related deaths is considerable, but much of it impact is related to chronic morbidity (WHO, 2016). To accurately reflect the impact of a disease not just in terms of lifes lost but also taking into account the morbidity caused by diseases such as schistosomiasis a disability weight is used. This is a weight factor reflecting the magnitude of the health loss associated with the 5 disease on a scale from 0-1, representing full health and death respectively (Salomon et al., 2015). As part of the Global Burden of Disease Study, schistosomiasis was attributed a disability weight of 0.6\% for the year 1990 (Murray \& Lopez, 1997), although other studies put the disability weight as high as 2-15\% (King et al., 2005). In the most recent Global Burden of Disease Study, the estimate of total disability-adjusted life years (DALYs) lost due to schistosomiasis was raised from 2.125 million to 3.309 million DALYs (Murray et al., 2012), reflecting the higher
estimates of disease prevalence as well as revised estimates of mortality and morbidity as measured by DALYs. Schistosomiasis transmission has been reported in 78 countries, including European countries such as Portugal and more recently France (Berry et al., 2014). Schistosomiasis is considered to be endemic in 52 out of 78 countries (WHO, 2018). Although sub-Saharan Africa is most affected, schistosomiasis is also found in countries along the Atlantic coast of South America and the Caribbean as well as several Southeast Asian countries (Gryseels et al., 2006).

### 1.3.1 Chemotherapy and control of schistosomiasis

Currently the only drug available to fight schistosomiasis effectively is praziquantel, which is used heavily in large parts of Africa with the declared aim of morbidity control (WHO, 2018). That means that rather than aiming to eradicate the disease in these areas, the aim is to reduce the intensity of the infection in the population and thereby lower the frequency of complications associated with schistosomiasis. The WHO considers schoolchildren to be target populations for these mass treatment programs, as well as at-risk adults such as fishermen or farmers who work in irrigation ditches and communities who heavily depend on water in endemic regions (WHO, 2018). Evidence has shown that pre-school children can also carry high intensity infections. For example Dabo et al. (2011) found between $15.7 \%$ of preschool children in different villages in Mali to have high intensity infections, determined by an egg count of $\geq 50$ eggs $/ \mathrm{ml}$ in their urine. However, there are concerns about the safety of praziquantel in very young children due to a lack of reliable safety data (Stothard
et al., 2013). This mass treatment strategy, although representing the most costeffective method in high-prevalence settings (WHO, 2018), has major limitations: Firstly, it does not eradicate schistosomiasis in the regions covered but, as stated above, aims to control morbidity. Secondly, it leaves the vector population unaffected, including infected snails. For this reason there is a risk of reinfection and so mass treatment needs to be repeated regularly to provide long-term benefit, which puts further strain on limited resources (WHO, 2018). Thirdly, due to mass drug administration, there is an increased pressure on parasite populations to become resistant to praziquantel - indeed reports of reduced sensitivity to praziquantel have been published in recent years (Crellen et al., 2016; Wang et al., 2014).

Unfortunately, despite decades of research into the development of a schistosomiasis vaccine, no successful formulation has been yet found (Hagan \& Sharaf, 2003; McManus \& Loukas, 2008). There is evidence that protective immunity against percutaneous infection with schistosomes can be raised with radiation-attenuated cercariae (Bickle, 2009; El Ridi \& Tallima, 2015). Reductions in worm burdens up to $40-60 \%$ in treated mice were observed (Bickle et al., 1979). However, no single- or multi-valent vaccine tested to date has been able to advance from clinical trials. As a result, the search for viable vaccine targets continues including "-omics" approaches such as transcriptomics, proteomics but also glycomics and immunomics for candidate generation (Loukas et al., 2011) and several promising candidates are being investigated (Merrifield et al., 2016). These include a fatty acid binding protein (Sm14), tetraspanin-2 (SmTSP-2), glutathione S-transferase (Sh28GST) and
calpain (Sm80) (Tebeje et al., 2016). While vaccines using Sm14, Sh28GST and SmTSP-2 have already been tested in humans (Bourke et al., 2014; Merrifield et al., 2016; Santini-Oliveira et al., 2016) the vaccine using calpain has been tested in mice and baboons (Ahmad et al., 2010; Ahmad et al., 2011) and is now undergoing preparations for human trials (Rojo et al., 2017).

### 1.3.2 Pathology of schistosomiasis

## Acute pathology

Individuals who are exposed to schistosomal cercariae for the first time, such as travellers or migrants are prone to developing acute symptoms in response to infection (Paris \& Caumes, 2010; Ross et al., 2007). It has been suggested that the low rate of acute schistosomiasis in exposed populations, especially children, is due to a combination of underdiagnosis and in-utero sensitization (Gryseels et al., 2006). Within the first hours or days after penetration of the skin by cercariae, some may develop a temporary rash or lesions at the site of penetration (Gryseels et al., 2006). Over the weeks or sometimes months following the infection, some individuals may experience an acute systemic hypersensitivity to the developing worms also known as Katayama fever (Ross et al., 2007); symptoms include fever, fatigue, myalgia, malaise, cough, eosinophilia, and lung lesions (Gryseels et al., 2006). Although most patients recover within 210 weeks, some go on to develop abdominal symptoms as well, including weight loss, diarrhoea, abdominal pain, hepatosplenomegaly, and rashes (Bottieau et al., 2006).

## Chronic pathology

As is the case for many infectious diseases, the severity of symptoms is determined by a combination of several factors: the intensity of infection, the host immune response and environmental factors. The sympthoms of chronic schistosomiasis include abdominal pain, diarrhea and rectal bleeding (or haematuria in the case of an $S$. haematobium infection). Over the course of the infection the patients can develop anaemia, hepatosplenomegaly, an enlargement of liver and spleen as the result of fibrosis, and periportal fibrosis.

Most of the chronic pathology caused by the infection is not inflicted by the adult worms. Instead it results from the host immune response against the eggs during their perivesicular or periintestinal migration or once they have become trapped in organs such as liver, spleen and lung (Gryseels et al., 2006). The human immune system responds to $S$. mansoni infections in a T helper 2-associated manner (Colley \& Secor, 2014). This includes the use of parasite-specific antibodies, eosinophils and alternatively activated macrophages (Barron \& Wynn, 2011; Colley \& Secor, 2014), driven by the release of interleukins 4 and 13 (Pagán \& Ramakrishnan, 2018). These interleukins help to modulate the immune repose to a state of chronic inflammation and the formation of granulomas around S. mansoni eggs (Colley \& Secor, 2013). The eggs play an active role in this process through the secretion of proteolytic enzymes that provoke an eosinophilic pro-inflammatory and granulomatous response (Cass et al., 2007; Jenkins et al., 2007; Everts et al., 2009). In the case of S. haematobium, the deposition of eggs around the bladder can also result in squamous cell carcinoma of the bladder (Nesi et al., 2015). In the liver, this immune response can lead to
fibrosis and later cirrhosis (Wynn, 2015). This, in turn, can result in potentially lethal pulmonary hypertension and oesophageal varices (Colley \& Secor, 2013). In other parts of the body this immune response can cause genital, urinary, intestinal and pulmonary schistosomiasis as well as neuroschistosomiasis (Gryseels et al., 2006). Individuals with genital schistosomiasis may have symptoms including inflammatory lesions in reproductive organs that can lead to infertility as well as increasing the transmission of sexually transmitted infections, such as HIV (Gryseels, 2012).

Apart from the potentially irreversible damage to the internal organs, schistosomiasis can have a range of more subtle effects. These effects include, but are not limited to, fatigue, stunted physical and cognitive development of young children, as well as anaemia and exacerbation of malnutrition (Mcgarvey, 2000; Sousa-Figueiredo et al., 2012). As these conditions affect large numbers of people in endemic areas, it becomes clear that successful intervention would be of great benefit to these communities (Gryseels et al., 2006).

### 1.4 Male-female interaction

The dependence of female $S$. mansoni on pairing with a male for sexual maturation is long established (Kunz, 2001). Mating usually occurs in a parallel fashion (anterior to anterior), but about $12 \%$ of S. mansoni pairs are found to be paired in a reverse orientation (Faust et al., 1934). Although it is usual for $S$. mansoni females to pair with one male only, it has been observed, both with freshly perfused worms as well as in vitro, that multiple males will clasp onto a
single female. (Basch, 1991). In other members of the family Schistosomatidae, the number of females paired with a single male can be greater. For example, Chu \& Cutress (1954) found male Austrobilharzia variglandis to be paired with 3 to 8 females at once. Furthermore, Armstrong (1965) found a male Heterobilharzia americana to be paired simultaneously with 29 female $S$. mansoni, all of which appeared to be sexually mature. Male S. mansoni have a propensity to pair and in the absence of females will clasp onto objects of similar shape and size to female worms, e.g. made from cotton or agar (Basch \& Nicolas, 1989). Even in vitro, worms pair or re-pair quickly: Michaels \& Prata (1968) observed that when keeping male and a female worms together in vitro, the proportion of paired worms increased steadily. Out of a total of 140 potential pairs, after 1 day in culture $20.7 \%$ of worms were paired, $84.2 \%$ after 2 days, $94.5 \%$ after 3 days and $100 \%$ after 5 days .

When trying to determine the nature of the stimulus that leads to female sexual maturation, the first processes to be examined were insemination as well as the transfer of metabolites, such as carbohydrates, cholesterol, lipids, amino acids and polypeptides, to the female (Basch, 1991). Shaw (1977) demonstrated that pairing alone is enough to induce some development of vitelline tissue and occasionally even formation of an egg, without insemination. To do so, he allowed females from single sex (SS) infection and males from MS infections to pair, noting changes in female morphology within 5-6 days, whilst showing that $\sim 85 \%$ of females remained unfertilised up to this point. Michaels (1969) also showed that males irradiated with X-rays readily paired and induced female maturation. Even without intact testes, this lead to successful female sexual
development and egg laying. The male stimulus was also shown not to be under the control of the cerebral ganglia of the nervous system, as decapitated males are still able to induce female maturation (Popiel \& Basch, 1984); however, as the authors stated, this does not unequivocally rule out involvement of the central nervous system, as parts of the nervous system in the rest of the body were found to remain functional (Popiel \& Basch, 1984). Furthermore, the stimulus is also not species-specific as females paired with males of other species (heterospecific pairing) will produce eggs, albeit at a reduced rate (Kunz, 2001).

Although the nature of the stimulation of female worms is unclear, it requires contact, occurs along the whole gynecophoral canal and is local, i.e. is not propagated longitudinally through the body of the female worm (Basch, 1991). The nature of the stimulus has been speculated to be physical, for example tactile, or involve transfer of hormones, nutrients and other signalling molecules (LoVerde et al., 2005). Several studies have provided evidence for nutrients playing a key role in supporting female fertility (Pearce \& Huang, 2015), especially the availability of red blood cells (Wang et al., 2015) and fatty acids (Huang et al., 2012). S. mansoni cannot synthesise fatty acids, relying instead on their host to provide them (Meyer et al., 1970). Metabolites such as glucose (Cornford \& Huot, 1981) and cholesterol (Popiel \& Basch, 1986) can be transferred through the gynecophoral canal to the female which may help to fulfil the female nutritional demands.

### 1.5 Molecular biology of male-female interaction

Several signalling pathways thought to be involved in stimulating the growth and maturation of female $S$. mansoni have been characterised, including the transforming growth factor (TGF)- $\beta$ /SMAD and the MAPK pathway (Beckmann et al., 2010). In the context of female maturation they serve to transmit growthinducing stimuli from the male worm to the nuclei of cells in the vitellarium and ovaries (Beckmann et al., 2010).

The TGF- $\beta$ pathway plays an important role in the development of multicellular organisms (Osman et al., 2006). TGF- $\beta$ is a polypeptide and a cytokine that helps to regulate cell proliferation, differentiation and apoptosis (Massagué, 2012). Signalling is initiated by transmembrane serine/threonine kinase receptors, the TGF- $\beta$ receptors I \& II (T $\beta$ RI \& T $\beta$ RII) (Osman et al., 2006). TGF- $\beta$ signalling also relies on SMAD proteins, which were first detected in Drosophila melanogaster (Sekelsky et al., 1995) and Caenorhabditis elegans (Savage et al., 1996) where they were termed "mothers against decapentaplegic" (MAD) and "small body size" (SMA), respectively. Proteins found to be homologues of these two are now called SMAD by merging the two names. SMADs form trimers of two R-SMAD and one co-SMAD molecule. These act as transcription factors to activate expression of downstream genes (Shi \& Massagué, 2003). Homologues of T $\beta$ Rs, SMADs, as well as of several other proteins that form part of the intracellular TGF- $\beta$ signalling pathway, have been discovered in schistosomes (Loverde et al., 2007). These include the T $\beta$ RI-regulating protein FKBP12 as well as the proteins SMAD2, a receptor regulated SMAD (R-SMAD) (Wu et al., 2001) and SMAD4, a
common-mediator-SMAD (co-SMAD) (Shi et al., 1997). Many of these genes have been shown to be expressed in the ovaries and vitellarium of female and in the testis of male worms (Beckmann et al., 2010).

To demonstrate the importance of TGF- $\beta$ signalling for female reproductive activity, Knobloch et al. (2007) exposed S. mansoni pairs in vitro to the synthetic T $\beta$ R-I inhibitor TRIKI and demonstrated a reduction in mitotic activity the vitelline cells of females by $46 \%$, as well as a $28 \%$ reduction of laid eggs. However, as higher concentrations of TRIKI did not lead to a greater reduction in mitosis and egg laying, the authors concluded that alternative signalling pathways must be involved in the development of the vitellarium (Knobloch et al., 2007).

Using another inhibitor, the Src-kinase specific herbimycin A, Knobloch et al. (2007, 2006) found egg laying in vitro to be reduced by $40-60 \%$ and mitotic activity in females (but not males) reduced by $25-75 \%$ in a dose-dependent manner. Src kinases are cytoplasmic tyrosine kinases (CTK) and hence belong to the superfamily of protein tyrosine kinases (Beckmann et al., 2010). CTKs are divided into eight subcategories based on the presence or absence of domains as well as their structural arrangements and several members of the CTKs have been discovered and found to be expressed in schistosome reproductive tissues (Beckmann et al., 2010).

The Src kinases SmTK3 (Kapp et al., 2004) and SmTK6 (Beckmann et al., 2011) have been localised to the gonads of S. mansoni, however, SmTK6 expression was
found to be absent from the vitellarian tissue (Beckmann et al., 2011). The Fyntype Src kinase SmTK5 is expressed in the gonads and vitellarium, and SmTK4, which belongs to the class of Syk kinases, is also expressed in the gonads but not the vitellarium (Knobloch et al., 2002).. SmTK3, SmTK4 and SmTK6 weree shown to interact directly with one another to regulate downstream signalling using yeast-2-hybrid screening (Beckmann et al., 2010; Kapp et al., 2004). Syk kinases regulate cell proliferation and progression through the cell cycle by activating expression of mitotic genes (Beckmann et al., 2010) but also by regulating cytokinesis and the cytoskeleton rearrangements (Mócsai et al., 2010). Syk kinases are activated by receptor tyrosine kinases (RTK), such as the epidermal growth factor receptor (EGFR) (Vicogne et al., 2004) or venus kinase receptors ( Vicogne et al., 2003). Sky kinase activation leads to the activation of a cascade of mitogen activating protein kinases, known as the MAPK signalling pathway (Qi \& Elion, 2005). At least 15 RTKs have been identified in the S. mansoni genome: This includes four EGFRs, two insulin receptors, two fibroblast growth factor receptors (FGFR), an Ephrin receptor, a RTK-like orphan receptor, a musclespecific kinase receptor, a cholecystokinin tetrapeptide receptor families as well as an unknown receptor (Andrade et al., 2011; Avelar et al., 2011). A variety of extracellular stimuli can activate the MAPK pathway through RTKs in the cell membrane. Through a series of kinases activating one another, a MAPK such as the extracellular responsive kinase (ERK) is activated (Qi, 2005). ERK translocates into the nucleus where it phosphorylates the transcription factor ELK-1, thereby allowing it to form a heterodimer with the serum response factor and activate transcription by binding to the promoter of target genes such as cFos in humans (Cavigelli et al., 1995).

Several components of the MAPK signalling cascade were discovered in the $S$. mansoni genom by in silico analysis (Andrade et al., 2011) and their biological role has been further characterised since then: In planarians, ERK is now known to play a central role in the regeneration of tissue by stem cells (Tasaki et al., 2011), a process thought to be similar to the growth of the female reproductive organs in S. mansoni in response to pairing (Collins \& Newmark, 2013), whereas in C. elegans the MAPK pathway is known to be important in several developmental events as well as establishing meiosis in the germ line (Sundaram, 2006). Andrade et al. (2014) demonstrated that RNAi using long dsRNA molecules can be used in vivo in S. mansoni to investigate the role of the MAPK pathway. They successfully knocked down ERK and found no effect on worm survival but a $44 \%$ reduction in hepatic egg count relative to a negative control, suggesting that MAPK may play a role in female fertility.

Other proteins involved in regulation of the MAPK pathway for which homologues have been found in S. mansoni include the adapter proteins SHC and growth factor receptor-bound protein 2 , which act by binding to the cytoplasmic portion of RTKs, and control recruitment of "Son of sevenless" (SOS), a guanine nucleotide exchange factor protein (Knobloch et al., 2007). This in turn activates the membrane associated GTPase called Ras by catalysing the exchange of GDP with GTP, thereby activating Ras which goes on to activate the MAPK cascade (Beckmann et al., 2010). Another protein, the GTPase-activating protein (GAP), promotes the exchange of GTP with GDP, thereby leading to deactivation of Ras, causing deactivation of the MAPK pathway (Beckmann et al., 2010). However,
activated Src kinases can phosphorylate GAP to down-regulate its inhibitory effect on the MAPK pathway (Downward, 1997; Qi, 2005).

In addition to RTKs, the integrin receptors $\alpha$ and $\beta$ have been found to activate focal adhesion kinase (FAK), another CTK (Guan, 1997; Mitra \& Schlaepfer, 2006). Integrins are composed of two non-covalently associated transmembrane glycoprotein subunits, $\alpha$ and $\beta$, and primarily serve to attach the cytoskeleton to the extracellular matrix (Alberts et al., 2007). They also play an important role in signalling by passing on extracellular stimuli to the FAK and often cooperate to promote cell growth, survival and proliferation (Alberts et al., 2007). S. mansoni integrin receptors and their role in reproduction were described by Beckmann et al. (2012) who found that integrin- $\beta-1$ was expressed in the reproductive organs of S. mansoni, co-localising with SmTK3, SmTK4 and SmTK6. Using a yeast-2hybrid screen the same authors showed that integrin- $\beta$-1 interacts with the SH2 domain of SmTK4 and with the SH3 domain of SmTK3 and SmTK6 (Beckmann et al., 2012). Recently, the interaction between integrins and the Venus Kinase Receptor 1, a RTK, was shown to regulate proliferation of oocytes by apoptosis in S. mansoni (Gelmedin et al., 2017).

Integrins often occur in complexes with tetraspanins (Tugues et al., 2013). These are a group of proteins characterised by four transmembrane domains, which form so called tetraspanin enriched microdomains which allow other molecules to assemble into signalling complexes (Tugues et al., 2013). Several tetraspanin homologues have been identified in S. mansoni, including members of the CD63 family of tetraspanins (Cogswell et al., 2012; Tran et al., 2010). One of the CD63
homologues is known to be expressed in a female-specific manner (Cogswell et al., 2012). In humans, CD63 has been shown to down-regulate apoptosis by interacting with the protein "tissue inhibitor of metalloprotease-1" (Jung et al., 2006).

Another group of kinases found in S. mansoni are polo like kinases (Long et al., 2010), also known as Cdc5, which have been shown to regulate cell cycle progression in a wide range of organisms such as Saccharomyces cerevisiae, D. melanogaster, C. elegans and humans (Chase et al., 2000; Llamazares et al., 1991; Toczyski et al., 1997). Polo-like kinases have a serine/threonine kinase domain as well as two signature motifs, known as polo boxes (Barr et al., 2004). In model organisms they have been found to tightly control the G2/M transition in the cell cycle by phosphorylation of Cdc25 which in turn activates CDKs by dephosphorylation (Roshak et al., 2000). This process drives the activation of mitotic events including centrosome maturation, bipolar spindle formation, activation of the anaphase promoting complex, chromosome segregation and actin ring formation in preparation for cytokinesis (Van De Weerdt \& Medema, 2006). Polo-like kinases themselves are regulated by a group called polo-like kinase kinases, one member of which has been found in S. mansoni and is a homologue of human protein Ste20 (Yan et al., 2007). Ste20-like kinases belong to the germinal center kinase subfamily and their function, like that of the integrin receptors, relates to the regulation of actin-mediated processes including cell shape and cytoskeletal rearrangements (Belkina et al., 2009).

### 1.6 Genomics \& Transcriptomics

### 1.6.1 Genome

S. mansoni is a diploid organism with seven pairs of autosomes, a pair of sex chromosomes and a mitochondrial genome (Swain et al., 2011). Schistosomes have a ZW determination, meaning that the male is homogametic (ZZ) and the female heterogametic (ZW) (Short \& Grossman, 1981).

Berriman et al. (2009) found the nuclear genome to be $30 \%$ larger than previously estimated, around 374.9 Mb , approximately one ninth of the human genome but considerably larger than the genome of $C$. elegans ( $\sim 98 \mathrm{Mbp}$ ) ( $C$. elegans Sequencing Consortium, 1998) or D. melanogaster ( $\sim 120 \mathrm{Mbp}$ ) (Adams et al., 2000). 40\% of the S. mansoni genome is made up of repetitive sequences, including 72 families of long-terminal repeat (LTR) and non-LTR transposons each, comprising $15 \%$ and $5 \%$ respectively of the whole genome. In the most recently published version of the genome its size was revidsed down to 364.5 Mb and the number of genes now stands at 10,852, having been revised down from 11,807 in the original genome paper, after more than $45 \%$ of gene models were modified (Protasio et al., 2012). These advances were due in part to RNASeq evidence that allowed for improved gene predictions and due to a less fragmented genome with fewer duplicated sequences that had resulted from polymorphism (Protasio et al., 2012). The current genome assembly consists of 9203 contigs with an average length of 39.4 kb , a N50 length of 78.3 kb - a measure of assembly quality indicating that $50 \%$ of the genome sequence was
contained on contigs greater or equal to 78.3 kb - and 885 scaffolds with an average length of 411.9 kb and a N50 length of 32.1 Mb (Protasio et al., 2012).

Assembly of the Z and W chromosomes proved to be difficult as there are large regions of homology where the chromosomes are indistinguishable the Z and W chromosomes assembled together in 34 scaffolds with 59 Mb in total (Protasio et al., 2012). The same authors used differences in coverage of male and female DNA to identify female-specific regions of the W chromosome. Overall, $30 \%$ of the $\mathrm{Z} / \mathrm{W}$ chromosome sequence was unique to the Z chromosome, and 23 Z specific genetic markers were identified in the assembled Z/W scaffolds (Protasio et al., 2012). 114 unplaced scaffolds, totalling approximately 1.1 Mb , were found to be W-specific but contained approximately $90 \%$ repetitive sequence including known female-specific repeats (Portela et al., 2010).

### 1.6.2 Transcriptomics of sex-specific schistosome biology

Due to its relevance for pathology and transmission, understanding the sexual dimorphism of schistosomes is critically important. This aspect of schistosome biology was and continues to be studied using different methods of transcriptome analysis (for example (Fitzpatrick et al., 2005; Lu et al., 2017)). In recent decades, several new methods of transcriptome analysis have become available, including methods based on quantitative real time PCR (qRT-PCR), expressed sequence tags (EST), serial analysis of gene expression (SAGE), cDNA microarrays and later RNA-seq as well as variations of these methods (Lowe et al., 2017). In the following paragraphs, I will summarise schistosome
transcriptomics, the development of methods and their use to address increasingly detailed biological questions.

Early papers to examine the differential expression of genes in male and female S. mansoni examined individual genes such as actin (Davis et al., 1985) or small groups of genes, due to a lack of high-throughput methods. In this case, Davis et al. (1985) used northern blot analysis to compare mRNA levels. The authors showed that two actin transcripts were more abundant in male worms than in females, cercariae and eggs. Using the same methodology the transcriptoion of the gene coding for the egg shell protein p48 was studied (Chen et al., 1992). The authors found it to be exclusively expressed in paired female worms. Furthermore Grevelding et al. (1997) identified three more genes, encoding egg shell protein p14, ferritin-1, and mucin-like protein A11, which they showed to only be expressed the vitelline tissue of paired female worms.

Thanks to the progress in human transcriptomics (Adams et al., 1991, 1992, 1993; Hoog, 1991), increasing availability of genomic data (Franco et al., 1995), programs and resources such as the WHO/UNDP/World Bank Schistosoma Genome Network (http://www.nhm.ac.uk/hosted_sites/schisto), the Schistosoma mansoni EST Genome Project (http://verjo18.iq.usp.br/schisto/) and the Institute for Genomic Research Schistosoma mansoni genome project (http://www.tigr.org/tdb/e2k1/sma1/index.shtml), it became feasible to design S. mansoni specific microarrays. This allowed scientists to examine hundreds of genes at the same time (Lowe et al., 2017). Hoffmann et al. (2002) used a cDNA microarray with 576 probes and were able to double the number of genes
known to be differentially expressed between male and female schistosomes, identifying sex-specific expression for twelve female- and four new male-specific transcripts.

One year later, 16000 ESTs and 163 full-length cDNA had been sequenced, when Verjovski-Almeida et al. (2003) generated ten times more ESTs and provided the first sequencing-based comprehensive overview of a schistosome transcriptome. However most transcripts were still not sequenced along their full length, instead rather small, unique nucleotide sequences (tags) were sequenced, which allowed the corresponding genes to be identified (Lowe et al., 2017)l.

Many of the subsequent publications that examined differences between male and female worms as well as paired and single worms used microarray or tag sequencing methods: Between 2004 and 2014 several such papers were published (Fitzpatrick et al., 2004; Fitzpatrick et al., 2005; Fitzpatrick \& Hoffmann, 2006; Leutner et al., 2013; Moertel et al., 2006; Sun et al., 2014) leading to a further expansion of genes known to be gender- or pairingassociated. When examining differences between male and female worms from the genus Schistosoma, the number of gender-associated genes discovered by such undertakings thus increased from 16 (four male- and twelve female-specific genes (Hoffmann et al., 2002) to 30 (eight male- and 22 female- associated genes) in S. japonicum (Fitzpatrick et al., 2004), then later 227 (86 male- and 141 female-specific genes) in S. mansoni (Fitzpatrick et al., 2005) and finally 2179 (1163 male- and 1016 female-specific genes in S. japonicum (Moertel et al., 2006) genes, an 136 -fold increase of genes known to be differentially expressed
between male and female worms within four years.

Due to these investigations, we now know the transcripts most differentially expressed between sexually mature male and female worms. These differences closely reflect the biology of this parasite, with sexually mature females upregulating transcritption of genes associated with egg production, such as the major egg antigens other eggshell proteins, p48 (chorion), as well as tyrosinases (Fitzpatrick \& Hoffmann, 2006). Male-specific genes on the other hand are dominated by tegument and muscle genes (e.g. tetraspanin genes, tegumental antigen as well as actin, dynein light chain 3 , myosin and tropomyosin) (Fitzpatrick et al., 2005, 2004; Moertel et al., 2006). These may reflect the role of the male worm in anchoring the female inside blood vessels, moving her to suitable egg deposition sites (Fitzpatrick et al., 2005).

The role of pairing on gene expression and the resulting sexual maturation has also generated considerable interest (Fitzpatrick \& Hoffmann, 2006; Leutner et al., 2013; Sun et al., 2014). A number of different comparisons have been made: first Fitzpatrick \& Hoffmann (2006) used a cDNA microarray to examine differential gene expression in seven week old adult males and sexually mature female from mixed sex (MS) and females from single sex (SS) infections. This allowed the author to identify 245 genes differentially expressed between females from MS infections (64 genes) and SS infections (181 genes), and 138 138 genes differentially expressed between males from equivalent infections (104 genes up-regulated in males from SS and 34 in males from MS infections). In 2013, Leutner et al. used a combination of oligonucleotide microarray and

SuperSAGE (a form of Serial Analysis of Gene Expression using high-throughput sequencing (Lowe et al., 2017)) to examine males from MS and SS infections (using the terms pairing-experienced and inexperienced). Their microarray analysis allowed them to discover a total of 526 genes, which were differentially expressed in MS (229 genes) and SS males (297 genes) whereas their SuperSAGE analysis only detected 288 genes ( 253 genes in MS males and 35 in SS males). The discrepancy was explained partially by the fact that expression for over 4000 (out of a total 6326 examined) genes was only detected by one of the two methods as well as the use of stringent significance thresholds (Leutner et al., 2013). The intersection of those two data sets contains a total of 29 genes, 21 of which had functional annotation at the time, from which 16 genes were upregulated in males from SS, and 5 in males from MS infections (Leutner et al., 2013). Sun et al. (2014) examined S. japonicum at 18 and 23 d.p.i. to get an insight into the early changes induced by pairing, as well as the changes taking place in females from SS and MS infections between 18 and 23 d.p.i. At 18 d.p.i. they found a total of 318 differentially expressed genes (241 in females from SS and 77 in females from MS infections). However, at 23 d.p.i. the number of differentially expressed genes had risen to 3446 genes ( 533 in females from MS and 2913 in females from SS infections) (Sun et al., 2014). The numbers of genes differentially expressed between females from 18 and 23 d.p.i. are also large: for females from SS infections, 2545 genes were found to be differentially expressed (2193 up-regulated in females from 18 d.p.i. and 352 up-regulated in females from 23 d.p.i.) and for females from MS infections, 1998 genes were found to be differentially expressed ( 740 up-regulated in females at 18 d.p.i. and 1258 upregulated at 23 d.p.i.) (Sun et al., 2014). Due to an apparent lack of replicates in
this study, it is hard to estimate how much biological variability there is, but a general trend can be seen clearly: The transcriptome of paired female worms (MS infections) becomes increasingly divergent from females that remain unpaired (SS infections) (Sun et al., 2014). As paired females mature sexually the differences between them and females from single sex females become more noticeable both morphologically (Fitzpatrick \& Hoffmann, 2006), but also at the transcriptome level and these differences increase as pairing continues until the paired female reaches complete sexual maturity around 5 weeks p.i. (Basch, 1991).

Recently, Wang et al. (2017) published a large RNA-Seq study in which they presented evidence that biogenic amines serve as the male stimulus for female sexual maturation. Having sequenced 48 S . japonicum transcriptomes from eight time points in the intra-mammalian stage (between 14-28 d.p.i.) and both sexes, with three biological replicates each, these authors found the expression of an aromatic-L-amino acid decarboxylase (AADC) to increase leading up to pairing, and showed the expression of AADC to be located in the gynecophoral canal by using whole mount in situ hybridisation (Wang et al., 2017). Furthermore the authors found an allatostatin-A receptor-like gene (AlstR), coding for an insectlike hormone receptor, to be involved in the maturation of female reproductive organs (Wang et al., 2017). Indeen, when AlstR was knocked down using RNAi, ovaries and vitelline glands failed to mature, in contrast to control females (Wang et al., 2017). Another study found evidence that histone modifications (H3K27me3) are different between male and female S. mansoni (Picard et al., 2016). The authors found these epigenetic modifications to correlate with gene
expression showed there to be a sex-biased dynamic of histone methylation, in particular a depletion of H3K27me3 along the transcription unit in male worms (Picard et al., 2016). However, as all RNA-Seq data in this study was derived from worms of SS infections, it remains to be seen if these results hold true for sexually mature females as well.

| Publication | Method | Species | Number of probes/read | Comparison | Results |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Hoffmann et al., 2002 | cDNA microarray | S. mansoni | 576 ESTs | Adult male vs female | 23 DEGs* |

${ }^{*}$ ) Including positive controls; ${ }^{* *}$ ) Results for Phillipine and Chinese Strains respectively; ${ }^{* * *}$ ) Not all comparisons summarised here

Table 1.1: Summary of the published literature on schistosome transcriptomic discussed in this chapter. The table provides the name of the first author and year of publication, the methods of transcirptomics used, the Schistosoma species examined in a given publication, the number of probes used (in the case of microarrays) or DNA reads sequenced (in the case of RNA-seq), the samples which were compared and finally the number of differentially expressed genes (DEGs) observed.

### 1.6.3 Methods of transcriptomics

This thesis relies heavily on gene expression data, including RNA sequencing (RNA-Seq) first and foremost, but also used quantitative reverse transcription polymerase chain reaction (qRT-PCR) data, which is often considered the gold standard for comparing gene expression, for validation of RNA-seq data. Microarray data is only used to briefly, by correlating previously published microarray data to RNA-seq data. The following section introduces these methods for measuring changes in the transcriptome as well as their strengths and weaknesses.

## Quantitative reverse transcription PCR

qRT-PCR is used frequently to compare expression of small numbers of genes between different samples. After reverse transcription of mRNA, the cDNA is used as template for a PCR reaction where, over the course of several rounds of amplification, the quantity of target cDNA is measured. This can for example be done using SybrGreen, a compound that fluoresces when bound to DNA. Over successive rounds of PCR this results in stronger fluorescence as more DNA has been produced. The quantities of DNA in the sample and control can then be compared to determine the relative abundances of the target sequence in the
cDNA. The method most commonly used for inferring differences in expression between samples is called $\Delta \Delta \mathrm{Ct}$ Calculation Method, and it makes use of one or more internal reference (IR) genes thought to be expressed at identical levels across all samples, to control for differences in the quantity of input cDNA (Kubista et al., 2006). The IR is used for normalisation of the amount of input cDNA between different samples, so that any differences between target gene expression observed after normalisation represents the treatment effect (see Chapter 2.2.5). qRT-PCR has been widely used to measure gene expression in schistosomes. For example it has been used to identify or validate genderspecific gene expression by comparing male and female samples (Hoffmann et al., 2002), pairing-induced gene expression by comparing cDNA samples from paired to those of virginal females (Fitzpatrick \& Hoffmann, 2006). Another example is the use of qRT-PCR to compare gene expression in different organs (Hahnel et al., 2014) and in RNAi knock-down experiments (Tran et al., 2010).

## Microarray

cDNA microarrays are a collection of DNA probes which are immobilised on a small chip to allow sample RNA (after reverse transcription to cDNA) to be bound by hybridisation with the complementary probe sequences. When applying sample cDNA to the microarray, the relative abundance of sample cDNA molecules is usually measured using fluorophore- or chemiluminescencelabelled probes (M. B. Miller \& Tang, 2009). It is worth noting that reference sequences have to be known prior to the production of the microarray probes (Lowe et al., 2017). This allows comparisons of transcript abundances of two or more experimental conditions. As in the case of qRT-PCR, stringent
normalisation is necessary to obtain accurate results. This includes measuring technical as well as biological variation across the transcriptome. Microarrays can be performed at very high throughput, due to the relatively low labour intensity (compared to RNA-seq), but they require a relatively large amount of mRNA input (about $1 \mu \mathrm{~g}$ of mRNA) (Lowe et al., 2017). This can limit the application of microarray, if the biological samples are difficult to obtain and very small in size.

## RNA sequencing

RNA-Seq relies on high-throughtput sequencing technology that can provide the sequences of vast numbers of short cDNA fragments to determine the abundance of cDNA molecules in each sample. Depending on the precise method used to make the cDNA library to be sequenced, the data may include information on the expression of not just messenger RNA (mRNA) but also non-coding RNAs such as ribosomal RNA (rRNA), transfer RNA (tRNA) and others. Careful normalisation is required for accurate results. The normalisation needs to correct for withinsample biases, caused by factors such as transcript length and GC-content, as well as between-sample biases, especially amount of sequenced cDNA. To correct within-sample biases RPKM (reads per kilobase of transcript per million mapped reads) or FPKM (fragments per kilobase of transcript per million mapped reads) are often chosen. This method scales the number of reads for a given gene to the length the given transcript as well as the overall number of reads across the whole transcriptome (Verk et al., 2013). However, it has been demonstrated that this method skews calls for differential expression in favour of longer transcripts as the number of reads mapping to a gene will be proportional to its length and
higher read counts give more statistical power to determine significant differences (Oshlack \& Wakefield, 2009). In cases where expression of a gene is compared across different samples (rather than different genes within one sample), only between-sample normalisation is necessary (Verk et al., 2013). In such cases sequencing yield is the most important variable to take into account. The sequencing yield, i.e. the total number of transcript reads generated during sequencing, has to be considered during the normalisation as it often differs between replicates and treatment groups. Rather than dividing the read count per gene by the total number of reads for a given sample, more robust methods are used that can take extreme expression values into account (Love et al., 2014). Such methods include the median-of-ratios (Love et al., 2014) and the trimmed mean of M-values method (Robinson et al., 2009). However in this context it is also important to consider the effect of relative abundances of mRNAs in a transcriptome. If the real expression of a target gene is identical in two samples, but its relative abundance is higher in one sample (for example due to a large number of other genes becoming down-regulated) the target gene will appear to be differentially expressed. Technical variation in transcriptome analysis is the measured differences introduced by the method or transcriptome analysis and sample handling, rather than differences in the underlying biology. Technical variation is thought to be smaller in RNA-Seq than in microarray technology (Marioni et al., 2008), biological variation has to be measured carefully to allow statistical inference of differential expression of a gene between two samples (Love et al., 2014). Furthermore, during the final steps of RNA-Seq library production, the cDNA is usually amplified using PCR. During this process some biases may be introduced as some GC-rich cDNA molecules don't become
amplified at the same rate as other molecules (Aird et al., 2011). However, this effect should be negligible when comparing expression of the same gene across different samples, as these samples should experience the same amplification biases at that locus.

RNA-Seq offers several advantages over microarrays. Firstly, microarrays rely on a library of probes that is pre-determined and based on existing genome annotations (Lowe et al., 2017). Thus genes that have not yet been discovered will be excluded from the analysis. Unlike microarrays, RNA-Seq data can be used to discover new transcripts and genes. This information can then be used to validate predicted gene models in the genome and contribute to improving the quality of genome annotation (Lowe et al., 2017). Secondly, RNA-Seq allows to detect splice variants, which can remain undiscovered in microarrays as, in many cases, different variants will hybridise with the same probe. Another advantage of RNA-Seq over microarray data is a larger dynamic range, which means accurate quantification of genes with very low or high expression (Zhao et al., 2014). In the absence of expression microarrays will often measure non-zero expression levels due to background noise such as non-specific hybridisation. Conversely at the high expression levels micro arrays can become saturated and unable resolve different expression levels anymore (Zhao et al., 2014). This allows for a more quantitative measurement of low and very high abundance cDNA using RNA-Seq (Wang et al., 2009).

## Comparison of RNA-Seq and proteomics

A discrepancy between mRNA and protein levels is to be expected in any organism as there are many mechanisms regulating the abundance of proteins in a cell (Maier et al., 2009). These include different efficiencies of mRNA cap binding proteins, the rate at which ribosomes are recruited to internal ribosome binding sites, codon usage, regulation by microRNAs, binding to RNA-binding proteins and mRNA stability which is mainly controlled by the mRNA poly-A tail (Vogel \& Marcotte, 2012). Protein abundance is also regulated further downstream of translation by degradation signals leading to ubiquitination and proteolysis (Vogel \& Marcotte, 2012). All these factors combined mean that there is not a perfect correlation between mRNA and protein levels (Maier et al., 2009). Schwanhaeusser et al. (2011) examined the correlation of steady-state mRNA and protein abundance in mouse fibroblasts, finding that, across 5028 genes, mRNA levels only explain between one and two thirds of the variation in protein levels observed $\left(\mathrm{R}^{2}=0.41\right)$. In human medulloblastoma cells, Vogel et al. (2010) reported that $66 \%$ of variation in protein levels could be explained by factors including mRNA concentration, UTR sequences and the coding sequence. Howver, these authors showed that mRNA concentration only explained $27 \%$ of the variance, $3^{\prime}$ UTRs $8 \%$ and that $31 \%$ was explained by the coding sequence. Nonetheless, Vogel \& Marcotte (2012) conclude that mRNA is a suitable proxy for the presence of a protein as mRNA levels detected by RNA-Seq directly correlated to the corresponding proteins in a proteomics experiment. However, work by Li et al. (2014) showed that due to problems with the normalisation of proteomics data in the aforementioned studies, mRNA concentrations predict around $84 \%$ of protein abundances (instead of $27 \%$ ). Furthermore, the mRNA
and protein abundance were shown to correlate more strongly after when cells responded to a stimulus (as opposed to a being in a steady state) (Koussounadis et al. 2015). In such situations the mRNA abundance of differentially expressed genes is even better correlated to their protein products (Koussounadis et al. 2015).

### 1.7 Aims of my project

The aim of this thesis is to explore and characterise the differences between male and female worms during their intra-mammalian development at the transcriptome level. Using the vast quantities of expression data that can be generated using RNA-Seq and the unprecedented detail it affords, what factors involved in the process of female maturation can be identified from the transcriptome? How does this change our understanding of the role that the male-female interaction plays in the transmission and pathology of the disease? In particular, this thesis addresses the differential expression of genes between male and female schistosomes during their intra-mammalian development including the changes in gene expression induced by the male-female interaction. Three main topics are examined in this thesis.

The first is the development of male and female worms inside the mammalian host. Particularly, when and how do male and female worms start to diverge at the transcriptome level? And similarly, what are the early differences of female worms in MS infections compared to SS infections at the transcriptome level?

Furthermore, what roles do some of the genes identified play in the female fertility? These results are presented in Chapter 3.

Next I wanted to discover the effect of cell proliferation and apoptosis on the maintenance of sexual maturity as well as regression of female reproductive tissues. Furthermore, how does pairing regulate these processes? Using an in vitro culture system of female worms in the presence or absence of male worms, the changes in expression of fertility-related genes were examined as well as genes that control apoptosis and cell proliferation. Results from this work comprise Chapter 4.

In Chapter 5, the transcriptomes of $S$. mansoni testes and ovaries were examined. This work was performed to learn how gene expression changed in the gonads in response to pairing. As pairing induces proliferation of the ovaries, it was of particular interest to us which transcriptome changes allowed for this proliferation to take place. These changes are obscured in the whole worms transcriptome by the larger vitellarium, but can be better resolved by examining the gonad transcriptomes.

Finally, Chapter 6 provides a summary of the findings in this thesis and places them in the context of the current understanding of the biology of schistosomes.

Chapter 2

Materials \& Methods

### 2.1 Parasite and snail maintenance

### 2.1.1 Parasites and snail origin

The species of schistosome used throughout this thesis was S. mansoni. For Chapter 3 \& 4 a parasite strain originally recovered from Puerto Rico were used. The parasites used in Chapter 5 originate from Liberia. Biomphalaria glabrata were used to maintain the $S$. mansoni life cycle throughout.

### 2.1.2 Miracidia infection of snails

Livers from S. mansoni infected (6-7 weeks p.i.) mice were soaked in sterile $1.2 \%$ NaCl solution with Penicillin/Streptomycin ( $100 \mathrm{U} / \mathrm{ml} ; 0.05 \mathrm{mg} / \mathrm{ml}$ ) at room temperature (RT) for 10 min . Livers were then transferred to a plasic beaker, and about 20 ml of sterile $1.2 \% \mathrm{NaCl}$ solution added. A blender (Bosch MSM 6B150) was used to homogenise the livers for 3 min at the lowest speed and the resulting liquid then filtered through two sieves with a pore size of $180 \mu \mathrm{~m}$, to remove larger liver particles, and then $45 \mu \mathrm{~m}$ to collect eggs. Eggs were collected in the lower sieve and further washed with $1.2 \% \mathrm{NaCl}$ solution. The eggs were then transferred to a volumetric flask with a narrow neck and the flask filled with Lepple water (see below). After incubating for 1 hour at $28^{\circ} \mathrm{C}$, all but the top 2 cm were covered in aluminium foil and the flask incubated for another 1 hour period. Next, miracidia were collected from the top layer of the solution. Five to six miracidia were used for mixed sex snail infections. For infections small snails ( 0.5 cm in diameter) were placed individually in the well of a 24 -well plate together with 1 ml of Lepple water. The miracidia were then carefully added to each well and left to infect the snail for 2 hours. Next the snails were placed back
into an aquarium for 5 weeks when snails were ready to be used to obtain cercariae.

## Lepple water (1x)

0.378 mM calcium chloride dihydrate
0.500 mM magnesium sulohate heptahydrate
0.025 mM potassium sulphate
0.500 mM sodium carbonate anhydrous
0.0002 mM ferric chloride

Lepple water was usually prepared as a 10 x concentrated solution and diluted with water prior to use.

To obtain mice infected with male or female schistosomes only, 50 snails were infected with single miracidia. In the four weeks following infection, the snails were exposed to light for two hours to shed clonal, single sex, cercariae (Tucker et al., 2013). Approximately 500 cercariae from each snail, as well as single male and a single female adult worm (positive controls) were processed for DNA extraction with a DNA Mini kit (Qiagen, 51304) PCR was used to identify sexspecific W2 regions on the (female-sepecific) W-chromosome using the rhodopsin gene as positive control gene (Lepesant et al., 2012). The following primers were used:

W2 primers:
FWD: CTGTTTCGAATTTCACACTTCA $\quad\left(\mathrm{T}_{\mathrm{m}}=61.7^{\circ} \mathrm{C}\right)$
REV: CATTCACAGTTTGGCGAACA $\quad\left(\mathrm{T}_{\mathrm{m}}=64.7^{\circ} \mathrm{C}\right)$

Rho primers:

| FWD: GACGGCCACACTAAAG | $\left(\mathrm{T}_{\mathrm{m}}=54.7^{\circ} \mathrm{C}\right)$ |
| :--- | :--- |
| REV: AGTAAAATGGTCACTGCTAT | $\left(\mathrm{T}_{\mathrm{m}}=52.8^{\circ} \mathrm{C}\right)$ |

PCR reactions were assembled using $10 \mu \mathrm{l}$ of HiFI Ready Mix (Kара, KK2602), 2.5 $\mu \mathrm{l}$ of genomic DNA solution, $1.0 \mu \mathrm{l}$ of the primer mix $(10 \mu \mathrm{M})$ and $6.5 \mu \mathrm{l}$ of $\mathrm{ddH}_{2} 0$ for a total of $20 \mu$ l. After denaturing the DNA for 5 min at $95^{\circ} \mathrm{C}$ the samples then
 Finally the samples were kept ay $72^{\circ} \mathrm{C}$ for 1 min .

The PCR products were run on an $1 \%$ agarose gel in TBE buffer at 80 V and 100 mA for 50 min . Female samples showed amplification in both the Rhodopsin- as well as W2-specific PCR reaction, whereas male samples only had an amplicon in the Rhodopsin-specific reaction.

Figure 2.1: The sex of cercariae from single-miracidium infections was determined by PCR. Male S. mansoni samples do not have an amplicon in the W chromosome specific region, whereas female $S$. mansoni samples do have an amplicon for the W specific reaction. The Rho reactions serve as a positive control and should have an amplicon regardless of sex. The cercariae from four snails (Cerc 1, 3, 4 and 5) were found to be female, the other (Cerc 2 and 6) male.

### 2.1.3 Detecting eggs in mouse livers

To determine whether single sex infections with only male or only female worms had been achieved, the livers of sacrificed mice were blended as described above.

Livers were transferred to a plasic beaker and homogenised using a blender (Bosch MSM 6B150) for 3 min at the lowest speed. The resulting liquid was then filtered through two sieves with a pore size of $180 \mu \mathrm{~m}$, to remove larger liver particles, and then $45 \mu \mathrm{~m}$ to collect eggs. If any eggs were found, the corresponding mouse was classed as having had a mixed sex infection, otherwise (if any worms had been recovered from the mouse by perfusion) the mouse was classed as having had a single sex infection.

### 2.1.4 Collection of cercariae

Infected snails were kept in a dark cabinet until cercariae were required. Then they were moved into small glass beakers with enough Lepple water to cover all snails and left under a bright light for one hour allowing the cercariae to emerge from the snails. After one hour, the water was carefully poured into 50 ml falcon tubes and the snails transferred back into their tanks in the dark cabinet. Cercariae numbers were estimated by taking the average count from five $10 \mu \mathrm{l}$ aliquots of the cercariae. The cercariae were killed with Lugol's iodine solution (Sigma, L6146) and then counted under a dissection microscope.

### 2.1.5 Infections and perfusions

All animal experiments were conducted under Home Office Project Licence No. 80/2596. All protocols were presented and approved by the Animal Welfare and Ethical Review Body (AWERB) of the Wellcome Trust Sanger Institute. The AWERB is constituted as required by the UK Animals (Scientific Procedures) Act 1986 Amendment Regulations 2012.

BALB/c mice were infected with about 250 mixed sex or single sex cercariae via intraperitoneal injection. After 18 to 49 d.p.i., the mice were euthanised by injection with an overdose of sodium pentothal and perfused to recover adult worms residing in the blood system. The worms used in Chapter 5 were grown in Syrian hamsters (Mesocricetus auratus); all animal work associated with

Chapter 5 was performed by the group of Prof. Dr. Christoph Grevelding (Justus-Liebig-University, BFS, Institute for Parasitology, Gie $ß e n, ~ G e r m a n y) . ~$

### 2.1.6 In vitro culture

In Chapter 3 (RNAi experiments), worms were maintained in vitro. Two experiments were set up, one with a total duration of seven days, and one with a 48 h incubation. For this latter experiment parasites were kept in supplemented DMEM media (see below) in a dark incubator at $37^{\circ} \mathrm{C}$ with $5 \% \mathrm{CO}_{2}$. In the case of the seven day incubation, the media was replaced every two days (see RNAi methods (2.2.2) for details). Furthermore, in Chapter 4, the effect of culture in DMEM media and Basch media on worm fertility was tested. The following recipes were used to prepare these media.

## Supplemented DMEM

0.02 M Hepes buffer (Sigma, 83264)

2 mM L-glutamine (Sigma, G7513)
10\% Fetal calf serum* (Sigma, F3297)
1x Antibiotic-Anitimycotic (ThermoFisher, 15240062)
DMEM media** (ThermoFisher, 10270106)
*) Fetal calf serum was heat-deactivated before use.
${ }^{* *}$ ) High glucose DMEM media was used.

## Basch media

In Chapter 4 worms were kept in vitro for seven days and Basch media (Basch, 1981). This media was used to was used to maintain female maturity as much as possible, as the female reproductive system usually regressed in culture. Worms were again maintained in an incubator at $37^{\circ} \mathrm{C}$ with $5 \% \mathrm{CO}_{2}$ and half the media was replaced every two days. Modified Basch media was prepared as described by Bhardwaj et al. (2011).

Directly prior to use, 1\% (by volume) horse red blood cells (RBCs) were added to the media. For this whole blood (ThermoFisher, SR0050) was first centrifuged at $4^{\circ} \mathrm{C}$ and 500 g for 10 min , then serum and the upper layer of blood were removed. The remaining RBCs were then suspended in BME (ThermoFisher, 41010-109) to produce a $50 \%$ stock solution of RBCs.

### 2.1.7 Isolation of $S$. mansoni gonads

The isolation of gonads was performed by the Dr. Zhigang Lu from the group of Prof. Dr. Christoph Grevelding (Justus-Liebig-University, BFS, Institute for Parasitology, Gießen, Germany) on worms from both MS and SS infections. It was performed as previously described by Hahnel et al. (2013), first using detergents (Brij35, Nonidet P40-Substitute, Tween80 and TritonX-405) to dissolve the tegument and then Type IV elastase to digest muscle tissue.

### 2.2 Molecular biology techniques

### 2.2.1 Cloning

If a transcripts was 1300 bp or shorter, primers were designed to clone the whole transcripts. Otherwise, a fragment of the transcript around 1000 bp in length was chosen and primers designed manually to clone that fragment. The primer pairs were designed to have similar melting temperatures to facilitate PCR reactions. Total RNA was isolated from adult worms using the Trizol reagents (Invitrogen, 15596026) (see 2.2.3). cDNA was synthesised using the SuperScript® III First-Strand Synthesis System (ThermoFisher, 18080051) using the manufacturer's protocol, with slight alterations. Firstly, reagents were incubated for 2 min at $25^{\circ} \mathrm{C}$ before $1 \mu \mathrm{l}$ of SuperScript ${ }^{\circledR}$ III was added. Secondly, samples were incubated at $25^{\circ} \mathrm{C}, 10 \mathrm{~min} ; 50^{\circ} \mathrm{C}, 60 \mathrm{~min} ; 70^{\circ} \mathrm{C}, 15 \mathrm{~min}$. cDNAs were amplified using the ReadMix Taq (Sigma, P4600) following manufacturer's instructions. The following primers were used:

CD63 receptor (Smp_155310) primers:
FWD: ATGTGTACTGTCGTATTGAGATTAAC $\quad\left(\mathrm{T}_{\mathrm{M}}=59.0^{\circ} \mathrm{C}\right)$
REV: TTAAGGATATCCAGTGGTTAGTATC $\quad\left(\mathrm{T}_{\mathrm{M}}=58.2^{\circ} \mathrm{C}\right)$
CD63 antigen (Smp_173150) primers:
FWD: ATGGCCTCTTTAAGCTGTGG

$$
\left(\mathrm{T}_{\mathrm{M}}=63.1^{\circ} \mathrm{C}\right)
$$

REV: TTAGTCAGAATCGCCAGATTTG

$$
\left(\mathrm{T}_{\mathrm{M}}=63.0^{\circ} \mathrm{C}\right)
$$

TSP-2 (Smp_181530) primers:
FWD: TTCTTCTTCGTTTCAGGGATGT

$$
\left(\mathrm{T}_{\mathrm{M}}=63.7^{\circ} \mathrm{C}\right)
$$

REV: TCACCGCGCTTTATAGCCAA
$\left(\mathrm{T}_{\mathrm{M}}=67.5^{\circ} \mathrm{C}\right)$

Boule (Smp_144860) primers:
FWD: GCCTTGGGGCATCTAAAGGT

$$
\left(\mathrm{T}_{\mathrm{M}}=66.1^{\circ} \mathrm{C}\right)
$$

REV: TGCTGCAGTGGATGCTGTTA

$$
\left(\mathrm{T}_{\mathrm{M}}=65.7^{\circ} \mathrm{C}\right)
$$

MXRA8b (Danio rerio; negative control) primers:
FWD: TCTTTCATGCAGGCCACAGT

$$
\left(\mathrm{T}_{\mathrm{M}}=65.8^{\circ} \mathrm{C}\right)
$$

REV: CCGGAACCAACCCGATTACA
( $\mathrm{T}_{\mathrm{M}}=68.8^{\circ} \mathrm{C}$ )

Target genes were amplified from the cDNA using 35 cycles of PCR $\left(95^{\circ} \mathrm{C}, 5\right.$ sec; variable temperature, $5 \mathrm{sec} ; 72^{\circ} \mathrm{C}, 30 \mathrm{sec}$ ) and finally 1 min at $72^{\circ} \mathrm{C}$. The annealing temperature was generally set to be $5^{\circ} \mathrm{C}$ lower than the higher melting temperature of the two primers (see above).

PCR products were then run on a $1 \%$ agarose gel in TBE buffer for 40 min at 100 V and 120 mA to confirm product size. The PCR reaction was then cleaned up using the QIAquick PCR Purification Kit (Qiagen, 28104) following manufacturer's instructions.

The required volumes of insert and vector ( $3000 \mathrm{bp} ; 50 \mathrm{ng} / \mu \mathrm{l}$ ) necessary for ligation at a 1:1 and 3:1 ratio were determined using Promega's Bio calculator. http://www.promega.com/a/apps/biomath/index.html?calc=ratio The pGEM-T easy vector system (Promega, A1360) was used following manufacturer's instructions.

The reactions were then incubated for 1.5 h at RT (rather than 1 h according to the protocol). Luria-Bertani (LB) Ampicillin ( $0.1 \mathrm{mg} / \mathrm{mL}$ ) agar plates were prepared by using 0.1 M Isopropyl $\beta$-D-1-thiogalactopyranoside (IPTG) (ThermoFisher, R1171) and $20 \mathrm{mg} / \mu \mathrm{l}$ 5-bromo-4-chloro-3-indolyl- $\beta$-Dgalactopyranoside (X-gal) (ThermoFisher, R0941) per plate which was spread with a sterile plate spreader. $50 \mu \mathrm{l}$ of competent cells (Invitrogen, C4-04003) were used for cloning, following the manufacturer's instructions.

Next, $950 \mu \mathrm{l}$ Super Optimal broth with Catabolite repression (SOC) medium (ThermoFisher, 15544034) were added to each tube of transformed bacteria; the samples were then placed in large 50 ml Falcon tubes and incubated at $37^{\circ} \mathrm{C}$ (shaking at 200 RPM) for 75 min . Transformed bacteria were removed from the incubator and centrifuged for 2 min at $1000 \mathrm{xg} .900 \mu \mathrm{l}$ of clear supernatant was removed and the remainder used to resuspend the cells. Approximately $50 \mu \mathrm{l}$ of suspended cells were plated onto the prepared LB agar plates and incubated at $37^{\circ} \mathrm{C}$ overnight.

### 2.2.2 RNA interference

This method relies on RNA molecules that are complementary to the target mRNA sequences. RNAi exploits a cellular mechanism to defend against RNA viruses to target specific mRNAs for degradation by the RNA-induced silencing complex, causing expression of the target gene to be reduced also known as "knocked down"..

The genes of interest, CD63a (Smp_173150) and CD63R (Smp_155310), as well as a positive control, TSP-2 (Smp_181530), were cloned (see 2.2.1) into the pGEM-T easy vector (Promega, A1360). The zebrafish (Danio rerio) gene encoding the matrix-remodelling associated protein 8 b , with no homology to $S$. mansoni proteins, was chosen as a negative control.

To create a linear template with T7 polymerase promoters on either end, primers were designed that had both a gene specific sequence (same as the original cloning primers) as well as the T 7 promoter sequence.

CD63 receptor primers $\left(\mathrm{T}_{\mathrm{m}}=54^{\circ} \mathrm{C}\right)$ :
FWD: TAATACGACTCACTATAGGGATGTGTACTGTCGTATTGAGATTAAC
REV: TAATACGACTCACTATAGGGGAACAACAAATTTGGCATC

CD63 antigen primers $\left(\mathrm{T}_{\mathrm{m}}=58^{\circ} \mathrm{C}\right)$ :
FDW: TAATACGACTCACTATAGGGATGGCCTCTTTAAGCTGTGG

REV: TAATACGACTCACTATAGGGCAGGGATTGTTTGTCCACTC
TSP-2 primers (Tran et al., 2010) $\left(\mathrm{T}_{\mathrm{m}}=59^{\circ} \mathrm{C}\right)$ :
FWD: TAATACGACTCACTATAGGGTGATTGTGGTTGGTGCACTT
REV: TAATACGACTCACTATAGGGGACCAATGCGAACAGAAACA
Negative control (MXRA8b) primers $\left(\mathrm{T}_{\mathrm{m}}=60^{\circ} \mathrm{C}\right)$ :
FWD: TAATACGACTCACTATAGGGTCTTTCATGCAGGCCACAGT
REV: TAATACGACTCACTATAGGGCCGGAACCAACCCGATTACA

All primers contain a T7 binding site (underlined). The PCR was performed following the instructions of the "MEGAscript T7 dsRNA" kit (ThermoFisher,

AM1626), first using the annealing temperatures (see above) of the gene-specific region of the primers for 5 cycles and then increasing the annealing temperature by $5^{\circ} \mathrm{C}$ for a further 30 cycles. The template was purified using a PCR clean up kit (Qiagen, 28104) following the manufacturer's instructions and was then used as input for the "MEGAscript T7 dsRNA" kit. Incubation of the in vitro transcription reaction was performed for 4 hours, and then the dsRNA was isolated from the reactions using the manufacturer's instructions. The kit used a column based method were the dsRNA is first precipitated with salts and ethanol, then bound to a column, washed several times and finally eluted. Length and concentration of the dsRNA was confirmed on the NanoDrop 1000 (ThermoFisher) and the Agilent tapestation.

## dsRNA soaking

Soaking was performed as described by Tran et al. (2010) with slight modifications. Briefly, worms were perfused from mice at 49 d.p.i. and paired couples cultured in Basch media while being soaked for seven days in $10 \mu \mathrm{~g} / \mathrm{ml}$ dsRNA. The following four dsRNA treatment groups were used: CD63R, CD63a, TSP-2 (positive control) and a negative control RNA (see above). Media was replaced every two days and new dsRNA added. After seven days worms were transferred into Trizol (Invitrogen, 15596026) for RNA extractions and the laid eggs counted in the plates.

## dsRNA electroporation

For electroporation, worms were washed carefully in DMEM (ThermoFisher, 10270106) following perfusions, placed in a microcentrifuge tube in $100 \mu \mathrm{l}$

DMEM. Then, $20 \mu \mathrm{l}$ of dsRNA solution ( $1 \mu \mathrm{~g} / \mathrm{ml}$ ) was added to the tube and incubated for 15 min at RT. The worms and the dsRNA solution were then transferred into 4 mm electroporation cuvettes (Bio-Rad).

20 msec square wave pulse was delivered to the worms using the Bio-Rad Gene Pulser Xcell system at 125 V ; worms were then transferred into pre-warmed Basch medium $\left(37^{\circ} \mathrm{C}\right)$ and cultured in vitro for 48 h . After 48 h the worms were transferred into Trizol (Invitrogen, 15596026) for RNA extractions and their eggs counted on the plates.

### 2.2.3 RNA extractions

Samples were placed in $500 \mu \mathrm{l}$ of Trizol (Invitrogen, 15596026) and stored at $80^{\circ} \mathrm{C}$ until further processing. Once ready, the samples were left to thaw on ice and then transferred to MagNA Lyser Green Beads tubes (Roche, 03358941001), containing small ceramic beads for mechanical homogenisation of tissue samples. The tubes were then placed in a FastPrep-24 instrument (MP Biomedicals) and homogenised three times for 20 sec at intensity 5 , with 5 min rest on ice between runs. Following homogenisation, samples were incubated for 5 min at RT to allow dissociation of nucleoprotein complexes. Approximately 0.2 volumes of chloroform:isoamyl alcohol (24:1) (Sigma, C0549) was added and the samples shaken vigorously. After a further 3 min incubation at RT the samples were centrifuged at 14000 g for 15 min at $4^{\circ} \mathrm{C}$.

Following centrifugation, the aqueous phase was transferred into a fresh RNase free micro centrifuge tube. Total RNA was isolated from the aqueous phase using
the RNA Clean \& Concentrator kit (Cambridge Bioscience, R1019) following manufacturer's instructions. Samples for qPCR were treated with DNase in the isolation columns as described in the kit protocol. Total RNA was eluted in $22 \mu \mathrm{l}$ of elution buffer and checked for degradation using an Nano Chip (Agilent, 50671512) on an Agilent 2100 Bioanalyzer. The RNA was deemed to be of good quality if one sharp ribosomal RNA peak could be seen. Samples were then stored at $-80^{\circ} \mathrm{C}$ until further processing.

Figure 2.1: Example of good quality extracted total RNA. The sharp peak of RNA at 2000 nucleotides ( nt ) is the ribosomal RNA peak.

### 2.2.4 cDNA synthesis

cDNA was used for cloning as well as qPCR. $11 \mu \mathrm{l}$ of DNase treated, full length total RNA was used as input. $1 \mu \mathrm{l}$ dNTPs ( 10 mM for each nucleotide) (NEB, N0447S) was added as well as $1 \mu \mathrm{l}$ oligo- $\mathrm{dT}_{18}$ primers ( $100 \mu \mathrm{M}$ ) (ThermoFisher, S0131). Samples were denatured for 5 min at $65^{\circ} \mathrm{C}$ and then cooled on ice. Then, $4 \mu \mathrm{l}$ 5x First Strand buffer (ThermoFisher), $1 \mu \mathrm{l}$ dithiothreitol ( 0.1 M ; Sigma) and $1 \mu \mathrm{l}$ SuperScript® III (ThermoFisher) were added. Samples were incubated at
$25^{\circ} \mathrm{C}, 10 \mathrm{~min} ; 50^{\circ} \mathrm{C}, 60 \mathrm{~min} ; 70^{\circ} \mathrm{C}, 15 \mathrm{~min}$ and then stored at $4^{\circ} \mathrm{C}$ until further processing.

### 2.2.5 qPCR

Primer3 (http://bioinfo.ut.ee/primer3/) was used to design qPCR primers (see Table 2.1) for the target genes $c d 63 r, c d 63 a$ and $t s p-2$. Settings were chosen to return primers providing approximately 100 bp long amplicons that did not overlap with the dsRNA probes used for RNAi (2.2.2). psmd4 (Smp_090340) was used as reference gene in all qPCR reactions. For quantification of RNAi efficiency, two more genes were used as internal reference, ndufv2 (Smp_069770) and gapdh (Smp_056970). Liu et al. (2012) found the house keeping genes $p s d m 4$ and ndufv2 to be particularly suitable as qPCR reference genes due to their stable expression.

| Target | FWD | REV | Efficiency |
| :---: | :--- | :--- | :---: | :---: |
| cd63r <br> Smp_155310 | CCCCTGTTGTAAAATGGATGCC | CCTGGACATGTTGGATCGAGA | $106 \%$ |
| cd63a <br> Smp_173150 | GTTGCCGTTTTAGTAGCGGC | CTCGGATAACACAGACAGCGA | $95 \%$ |
| tsp-2 <br> Smp_181530 | CGAAATTGAACCCCCACTAC | CATGCTCCAAACATCCCTAAA | $97 \%$ |
| psdm4 <br> Smp_000740 | CAAAGTTACAACGAGTTTCTGGCTCT | TGGCGTTTGCGATTTGCCAT |  |
| ndufv2 <br> Smp_069770 | TGGAATGCCTTGGAGCTTGTG | TCCGCTTTGTGGACCAGGTT | $104 \%$ |
| gapdh <br> Smp_056970 | TGTGAAAGAGATCCAGCAAAC | GATATTACCTGAGCTTTATCAATGG | $101 \%$ |

Table 2.1: List of qPCR targets and their forward and reverse primers. $t s p-2$ primer sequences were first described by Tran et al. (2010). Primer efficiencies were calculated using a standard curve.

Primer efficiencies were determined using a dilution series of primer concentrations as described by the manufacturer (Applied Biosystems, 2010). All primer pairs were found to have an efficiency between 90-110\%.

The qPCR was performed using KAPA SYBR FAST universal qPCR kit (KAPA Biosystems), following the manufacturer instructions. All cDNA samples were run in triplicates, as well as a triplicate negative control without cDNA template and a control with total RNA instead of cDNA to detect genomic DNA contamination. If genomic DNA has also been extracted during the RNA extraction, it could cause a false positive signal; the total RNA used in this control was not reverse transcribed and therefore should not allow for PCR amplification.

All reactions were $20 \mu \mathrm{l}$ in volume and performed in sealed MicroAmp 48-Well skirted PCR plates (ThermoFisher, 4375816) and briefly centrifuged to remove bubbles. qPCR reactions were performed in an Applied Biosystems StepOnePlus machine using the thermocycling conditions recommended by the manufacturer (KAPA Biosystems, 2016) (denaturation: $95^{\circ} \mathrm{C}, 3 \mathrm{~min}$; then 40 cycles of: $95^{\circ} \mathrm{C}, 1$ sec; $60^{\circ} \mathrm{C}, 20 \mathrm{sec}$ ). The amplification data was analysed and plotted manually in Microsoft EXCEL (v14.2.3) using the $\Delta \Delta C t$ method (Livak \& Schmittgen, 2001).

Initially the relative difference in expression between the internal reference and target gene was measured for both treated and control samples:
$\Delta \mathrm{Ct}_{\text {treated }}=\mathrm{Ct}_{\text {Internal reference, treated }}-\mathrm{Ct}_{\text {target gene, }}$, treated
$\Delta \mathrm{Cq}_{\text {control }}=\mathrm{Ct}_{\text {Internal reference, control }}-\mathrm{Ct}_{\text {target gene, control }}$

For multiple reference genes the average Ct value was calculated:
$\mathrm{Ct}_{\text {reference gene }}=\left(\mathrm{Ct}_{\text {GAPDH }}+\mathrm{Ct}_{\text {PSMD } 4}+\mathrm{Ct}_{\text {NDUFV2 }}\right) / 3$

Finally to find the relative difference in gene expression:
$\Delta \Delta \mathrm{Cq}=\operatorname{mean}\left(\Delta \mathrm{Ct}_{\text {treated }}\right)-\operatorname{mean}\left(\Delta \mathrm{Ct}_{\text {control }}\right)$

The fold-change was then be calculated as follows:
Fold-change $=2 \wedge \Delta \Delta \mathrm{Ct}$

### 2.2.6 Dot blot

To measure the efficiency of DIG labelling in the RNA probe, I used a dot blot assay, as described by Zimmerman et al. (2013). Briefly, serially diluted RNA probes were applied to a nylon membrane (Sigma, 11209272001) and crosslinked using UV light. The membrane was washed with maleic acid buffer, treated with blocking buffer and exposed to an anti-DIG antibody (Sigma, 11093274910) with a conjugated alkaline phosphatase enzyme ( $150 \mathrm{mU} / \mathrm{ml}$ ) in blocking buffer. Samples were developed until the desired signal was reached.

### 2.2.7 Whole mount in situ hybridisation

Whole mount in situ hybridisations (WISH) were performed using a protocol provided by Dr. James Collins, (UTSouthwestern, Department of Pharmacology, Dallas, Texas). For the in vitro synthesis of DIG-labelled RNA probes, the insert of the pGEM-T easy plasmid (Promega, A1360) was amplified using M13 primers
(Sigma, P3098; Sigma, P2973). The amplicon included the insert flanked by a T7 and a SP6 promoter on either side to allow synthesis of a sense (negative control) and an anti-sense probe $\left(95^{\circ} \mathrm{C}, 5 \mathrm{sec} ; 50^{\circ} \mathrm{C} 5\right.$ sec; $72^{\circ} \mathrm{C}$, 30 sec for 35 cycles, then $72^{\circ} \mathrm{C}, 1 \mathrm{~min}$ ).

The amplicon was then purified using a PCR purification Kit (Qiagen, 28104) and the DNA template concentration was measured using the Qubit 2.0 system (ThermoFisher).

A DIG RNA labelling KIT (Roche, 11175025910) was then used to synthesise DIG-labelled probes from the amplicons according to the manufacturer's protocol.

The solution was then cleaned up using the Cambridge Bioscience RNA clean and concentrator kit following manufacturer's instructions. Probe quality and concentration were determined using the Agilent Tapestation and the NanoDrop 1000 (ThermoFisher). DIG-labeling efficiency was tested using a dot blot test (see 2.2.9).

## 1) Preserving specimens

Parasites were collected by perfusion from mice seven weeks after infection with 250 mixed sex cercariae. The worms were then washed with DMEM to remove host material. Once clean, worms were killed using 0.6 M magnesium chloride for about 1 min and fixed for 4 h at room temperature in solution of $4 \%$ formaldehyde and $0.3 \%$ Triton-X 100 in phosphate buffered saline (PBSTx).

Next, the worms were rinsed with PBSTx, placed in $50 \%$ methanol in PBSTx for 5 $\min$ on a gentle shaker and then transferred to 50 ml tube with $100 \%$ methanol and stored at $-20^{\circ} \mathrm{C}$ until needed.

The protocol for whole mount in situ hybridisation was run over 3 days; on day 1 the DIG-RNA probe is hybridised to the target RNA, on day 2 the DIG label is bound by the antibody and on day 3 , the alkaline phosphatase on the antibody is used for detection.

## 2) Permeabilisation \& hybridisation with probe

Samples were rehydrated in $50 \%$ methanol in PBSTx for 5 min on a gentle shaker and then for 5 min in PBSTx at RT. Pigments were removed, especially from the guts and the vitellarian tissue of female worms by placing the worms in bleaching solution for 1 hour at RT under bright light. Next, samples were placed in small baskets, transferred to 24-well plates and rinsed in PBSTx. The baskets were used throughout the protocol to allow quicker and less damaging transfer of specimens between different buffers and solutions. The worms were permeabilised with proteinase $\mathrm{K}(5 \mathrm{ug} / \mathrm{ml})$ in PBSTx for 30 min at RT, without shaking. Following proteinase K treatment, the worms were rinsed in PBSTx and then fixed again in 4\% formaldehyde in PBSTx for 10 min at RT. Then, the worms were transferred briefly to PBSTx and washed in a 50\% PBSTx:50\% PreHyb buffer solution for 5 min at RT while being gently shaken. The washing solution was then replaced with pre-warmed 100\% PreHyb buffer and samples incubated at $52^{\circ} \mathrm{C}$ for 2 h while gently shaking. 1 h prior to adding the probe, 1000 ng of DIG-RNA probe was mixed with $500 \mu \mathrm{l}$ of hybridisation buffer and heated to
$72^{\circ} \mathrm{C}$ for 5 min to denature the RNA probe using a heat block (Stuart scientific, SBH130D). The probe was then allowed to cool slowly to $52^{\circ} \mathrm{C}$ in the heat block and was held at that temperature until needed. The PreHyb buffer was then replaced with the hybridisation buffer with the probe. Next, the samples and probes were allowed to hybridise overnight at $52^{\circ} \mathrm{C}$ while being gently shaken.

## 3) Removal of excess probe \& incubation with antibody

The hybridisation buffer was removed and samples washed at $52^{\circ} \mathrm{C}$ with the preheated solutions of wash hybridisation buffer ( $2 \times 30 \mathrm{~min}$ ), 2 x saline sodium citrate (SSC) buffer and $0.1 \%$ triton-X ( $2 \times 30 \mathrm{~min}$ ), and $0.2 \times$ SSC buffer and $0.1 \%$ triton-X ( $2 \times 30 \mathrm{~min}$ ); finally, worms were washed twice in Tris-NaCl-Tween (TNT) buffer at RT while gently shaking. Samples were transferred to blocking solution for 2 h at RT, still shaking. Next, samples were transferred to blocking solution with anti-DIG-alkaline phosphatase antibody (1:2000 dilution) and incubated at $4^{\circ} \mathrm{C}$ overnight whilst gently shaking.

## 4) Removal of excess antibody \& developing AP staining

Next, the samples were washed six times for 10 min at RT in TNT buffer.
Then, samples were developed in alkaline phosphatase (AP) buffer with nitro blue tetrazolium and 5-bromo-4-chloro-3-indolyl-phosphate (NBT/BCIP, Sigma, 11681451001) until the desired signal intensity had been reached. To stop the reaction, samples were transferred to PBSTx and placed in 100\% ethanol for 1020 min at RT. Samples were then removed form the ethanol, placed back in PBSTx for about 5 min and then stored in 80\% glycerol in PBS.

### 2.2.8 Imaging of WISH specimen - light microscopy

A Leica M205 FA dissection microscope was used to examine the prepared specimen after staining, images were captured with a Leica DFC 340 FX digital camera.

### 2.3 RNA-Seq library preparation \& sequencing

cDNA libraries were produced from pools of male or female worms, with the exception of the libraries in Chapter 4, where individual worms of both sexes were used, each representing a biological replicate. In the case of pooled worms, all worms originated from the same mouse, forming a biological replicate.

### 2.3.1 mRNA selection

100 ng of total RNA was used for each RNA-Seq libraries made from pooled worms (Chapter $3 \& 5$ ). For the cDNA libraries produced from single worms (Chapter 4) only 50 ng of total RNA was available per sample. Oligo dT beads (ThermoFisher, 61002) were used to increase the mRNA content of the samples, following the manufacturer's instruction. The method make use of magnetic beads covered in oligo dT molecules, to capture the mRNA by binding to the polyA tails. The rRNA which is not bound is then be washed off.

### 2.3.2 mRNA fragmentation

mRNA was made up to $200 \mu \mathrm{l}$ and sheared to around 200 bases using a AFA Covaris focused sonicator (Settings: Duty cycle - 10\%; Intensity - 5; time - 60 sec; NB: Duty cycle refers to the proportion of treatment time during which the acoustic burst is active).

### 2.3.3 Reverse transcription

Similarly to the cDNA synthesis step in the cloning section (2.2.1), RNA was used to create cDNA in this step. However, in this step the mRNA had been isolated (2.3.1) as well as fragmented (2.3.2) and rather than using oligo-dT primers, random hexamer primers (NEB, S1330S) were used to reverse transcribe all fragments. $1 \mu \mathrm{l}$ random primers ( $3 \mu \mathrm{~g} / \mathrm{ml}$ ) and $1 \mu \mathrm{l}$ dNTPs ( 10 mM for each dNTP) (NEB, N0446S) were added to11 $\mu \mathrm{l}$ of fragmented RNA. The mixture was denatured at $65^{\circ} \mathrm{C}$ for 5 min and chilled on ice. Next, $4 \mu \mathrm{l}$ of 5x First Strand buffer (NEB, E6114), $1 \mu \mathrm{l}$ of dithiothreitol ( 0.1 M ; Sigma, D0632) and $1 \mu \mathrm{l}$ of RNase inhibitor ( $40 \mathrm{U} / \mathrm{\mu l}$; ThermoFischer, 10777019 ) were added. The sample was incubated at RT for 2 min following which $1 \mu \mathrm{l}$ of SuperScript® III ( $200 \mathrm{U} / \mu \mathrm{l}$; ThermoFischer, 18080093) enzyme was added, to a total volume of $20 \mu \mathrm{l}$. The sample was then incubated in a thermocycler $\left(25^{\circ} \mathrm{C}, 10 \mathrm{~min} ; 50^{\circ} \mathrm{C}, 60 \mathrm{~min} ; 70^{\circ} \mathrm{C}\right.$, 15 min ). This denatures the SuperScript $®$ III enzyme but leaves the RNA/DNA duplex intact. After this step, the RNA/DNA duplex was cleaned using the RNAClean XP beads (Beckman Coulter, A63987) following manufacturer's instructions to remove any leftover dTTP nucleotides.

### 2.3.4 Second strand DNA synthesis

Second strand synthesis was performed with dUTP rather than dTTP allowing the two DNA strands to be differentiated into the sense strand (mRNA sequence - dUTP labelled) and antisense strand (complementary to mRNA - dTTP labelled). $22.6 \mu \mathrm{l}$ of RNA/DNA duplex from the last step were mixed with $3 \mu \mathrm{l}$ of buffer 2 (NEB, B7002S), $2 \mu \mathrm{l}$ dNTP mix (dUTP, dATP; dGTP; dCTP at 10 mM each) (NEB, E6114), $0.4 \mu \mathrm{l}$ RNase $\mathrm{H}(5000 \mathrm{U} / \mathrm{ml})(\mathrm{NEB}, \mathrm{M} 0297 \mathrm{~S})$ to nick (i.e. create a break in) the RNA strand, allowing the remaining RNA fragments to act as primers) and $2 \mu \mathrm{l}$ of DNA pol I ( $5000 \mathrm{U} / \mathrm{ml}$ ) (NEB, M0210S). The sample was incubated at $16^{\circ} \mathrm{C}$ for 2.5 h , then held at $4^{\circ} \mathrm{C}$. After second strand synthesis, the sample was cleaned using AMPure XP beads (Agencourt, AQ 60050) (at a ratio of 1 volume of sample to 1.8 volumes of beads). The sample was resuspended in 40 $\mu \mathrm{l}$ of water at the end of the bead purification protocol.

### 2.3.5 End repair, dA tailing, adapter ligation, size selection

The Sanger Sequencing Kit I (NEB, E6000B-SS) was used to perform end repair, dA tailing, adapter ligation and size selection of the cDNA. All steps were performed following the manufacturer's instructions.

In the next step, the Uracil-specific excision reagent (USER) enzyme (NEB, M5505S) was used to digest the second strand of all DNA molecules in the sample. For this, $1 \mu \mathrm{l}$ of USER enzyme was added to $10 \mu \mathrm{l}$ of library. The sample was then incubated in a thermo cycler for 15 min at $37^{\circ} \mathrm{C}$, then for 10 min at $95^{\circ} \mathrm{C}$, and finally held at $4^{\circ} \mathrm{C}$.

### 2.3.6 PCR amplification

After removal of primer dimers and digestion with the USER enzyme, the sample was amplified to reach a sufficiently high DNA concentration for sequencing. For this, $25 \mu$ of 2 x KAPA HIFI HS Master mix was added to $22 \mu \mathrm{l}$ of cDNA as well as $1 \mu \mathrm{l}$ each of PE 1.0 Illumina primer ( 10 mM ), Illumina index primer ( 10 mM ), and water. A unique barcode sequence was added to the cDNAs of each sample using the pCR primer. This allowed DNA sequences to be assigned to one sample in silico once sequencing was complete. This tagging allowed for mixing of libraries before sequencing, helping to control for biases, which could otherwise be introduced by differences across sequencing lane and runs. The sample was then amplified using a thermocycler (denaturation $95^{\circ} \mathrm{C}, 5 \mathrm{~min}$; 10 cycles of $95^{\circ} \mathrm{C}, 20$ sec; $60^{\circ} \mathrm{C}, 15 \mathrm{sec} ; 72^{\circ} \mathrm{C}, 60 \mathrm{sec}$; and next $72^{\circ} \mathrm{C}, 5 \mathrm{~min}$ ). Following the PCR , the samples were size selected, using 0.8 x sample volume of Agencourt AMPure XP beads following manufacturer's instructions to remove adapter dimers, which were amplified by the PCR reaction.

### 2.3.7 Sequencing

All samples were sequenced on a Illumina HiSeq 2500 platform. Samples in Chapter 3 \& 4 ( 60 and 70 samples respectively) were sequenced in three sequencing runs (six lanes in total). The biological replicates for each condition were distributed as evenly as possible across the runs. The 24 samples in Chapter 5 on the other hand were all sequenced together in one run (two lanes in total). Paired-end 100 bp reads were generated.

### 2.4 Bioinformatics

### 2.4.1 Aligning RNA-Seq reads to the genome

Tophat2 (v2.0.8b) was used to map RNA-Seq data to version 5.2 of the $S$. mansoni genome (Protasio et al., 2012). RNA-Seq reads span splice junctions where introns have been removed from the transcript. Many mapping tools do not take splicing into account when mapping reads to the genome as they are specialised for mapping genomic DNA reads. Tophat2 was specifically designed for RNA-Seq data to allow for optimal mapping of RNA-Seq data to the genome several parameters had to be set manually. By default, Tophat2 distributes a read that maps to multiple locations in the genome randomly to one of those locations. In this case this is undesirable as it could create the appearance of expression in loci that are not expressed, therefore the parameter was set to allow only for uniquely matching reads to be mapped ( -g 1 ). Next, the appropriate library type was specified (--library-type fr-firststrand), based on the preparation method using dUTP. Also based on the method of library preparation, the expected (mean) inner distance between mate pairs was set to 200 (-r 200) and the mate standard deviation was set to 100 (--mate-std-dev 100). To accurately map spliced reads the minimum length of sequence on either side of the splice junction was set to be at least six bases long (-a 6). Finally, the minimum and maximum lengths of introns were also specified as 10 and 40,000 bases respectively (-i 10 -I 40000) and microexons, exons as short as 3 base pairs which are difficult to detect without specialised algorithms (Volfovsky et al., 2003), were allowed for (--microexon-search). The output of this mapping of

RNA-seq data to the $S$. mansoni genome was provided in Binary sequence Aligned Map (BAM) format.

### 2.4.2 Sorting and merging of BAM files

SAMtools (v0.1.19) was used for the processing of mapped RNA-seq data in BAM format (Li et al., 2009). All BAM files were sorted, and the two BAM files (one for each lane of Illumina HiSeq 2500) corresponding to each sample merged, generating a single BAM file per sample.

### 2.4.3 Counting reads

HTSeq (v0.5.4) was used to summarise the mapped data and produce a list of read counts per gene for each sample (Anders et al., 2015). Using a file in Gene Transfer Formate (GTF) as reference for gene boundaries, HTSeq takes into account the strandedness of the data, only counting reads in the orientation of the mRNA and not of antisense RNA. Reads were also only counted for the longest splice variant of each gene to avoid complications in regions where the splice variants overlap and reads could not be unambiguously assigned.

### 2.4.4 Differential gene expression analysis

RNA-Seq data was analysed in all three results Chapter (3, 4 \& 5) to identify differentially expressed genes across groups of samples in $R$ (v3.2.2) (R Core Team, 2015) using DESeq2 Love et al. (2014). DESeq2 was created specifically to address the challenges, i.e. small numbers of replicates, large dynamic range and
the presence of outliers within the replicates (Love et al., 2014), that arise when analysing high throughput sequencing data, such as RNA-Seq data.

## Model and normalisation

Using the output of HTSeq, the number of unambiguously mapped reads per gene, a count matrix is created containing the read count for each gene in each sample. DESeq2 fits a Generalised Linear Model (GLM) for each gene. It models the read counts to follow a negative binomial distribution and calculates a size factor using the median-of-ratios method described in DESeq (Love et al., 2014). This corrects for the depth of sequencing across the different samples, allowing them to be compared against one another.

## Empirical Bayes shrinkage for dispersion estimation

To model the variability between replicates, DESeq2 estimates a dispersion parameter, which is critical for proper statistical inference of differential expression. To do so, first the gene-wise dispersion is estimated using maximumlikelihood, then DESeq2 uses this information to estimate the expected dispersion value for genes of a given expression strength by fitting a smooth curve through the distribution of dispersion. DESeq2 then "shrinks the genewise dispersion estimates toward the values predicted" to obtain final dispersion values.

## Empirical Bayes shrinkage for fold-change estimation

One of the biggest challenges when calculating fold changes using HTS data is the strong variance especially for genes with low read counts where the signal to
noise ratio is less favourable. DESeq2 shrinks log fold-change (LFC) estimates towards zero so that shrinkage is stronger for genes with low read counts, high dispersion, or fewer degrees of freedom. This is achieved by fitting each of the GLMs to obtain a maximum-likelihood estimation of the LFC and then fitting a zero-centred normalised distribution of all LFC. This distribution is then used in another round of GLM fitting, and the corrected estimates are kept as final LFC estimates.

## Automatic independent filtering

As differential expression of over $10,000 \mathrm{~S}$. mansoni genes were examined in each RNA-seq experiment, multiple testing adjustments were performed to reduce false positive results using the Benjamini and Hochberg method (Benjamini \& Hochberg, 1995). The automatic independent filtering method used by DESeq2 was designed to remove genes from the analysis that have little or no change of being differentially expressed. Importantly, these genes were excluded from further analysis using criteria independent of the statistics used to determine differential expression. The filtering relies on average expression strength for filtering, removing lowly expressed genes first. By default DESeq2 removes as many genes from the analysis as necessary to maximise the number of genes found to be differentially expressed at the specified false discovery rate (FDR) value (default 10\%). In this thesis the automatic independent filtering was most prominently used in Chapter 4 where high dispersion of gene expression presented a challenge for the identification of differentially expressed genes.

## Detection of count outliers

To reduce the impact of outliers on the average distribution of dispersion and log fold change, DESeq2 detects and removes individual outliers that do not fit the assumptions of the model such as a replicate with a read count several orders of magnitude higher than all other samples. To achieve this, DESeq2 uses a standard outlier diagnostic called Cook's distance. It measures how much the GLM for a given gene would be affected, if a particular sample was removed. However, this could only be done were three or more replicates were available for a given condition, as outlier status cannot be determined otherwise.

### 2.4.5 Correlation of RNA-Seq data with microarray data

To give an estimate of the reproducibility of the RNA-Seq data from Chapter 5 whole male and female worms as well as isolated S. mansoni gonads - sequencing data were compared to the microarray signal intensity of comparable samples published by Nawaratna et al. (2011). Microarray probe sequences were obtained from the Gene Expression Omnibus public database (accession numbers: GPL10875 \& GSE23942). Probe sequences were mapped to the $S$. mansoni genome (version 5.2) using bowtie (v1.1.0), a fast and memory-efficient mapping tool for short reads (Langmead et al., 2009), using default settings. A GTF file that contained the location of each mapped probe in the genome was created using the genome coordinates for each sequence from the BAM file and a custom python script. The number of RNA-Seq reads mapped to the microarray probe sequences was then counted as described in "Counting reads (HTSeqcount)" (2.4.3), using the newly created GTF file as reference. The number of RNA-Seq reads mapped to the probes was then compared to the normalised
signal intensity measured for the probe as reported by Nawaratna et al. (2011). The correlation coefficient was calculated for the RNA-Seq and microaarray signal using the correlation function in R ( R Core Team, 2015).

### 2.4.6 Principal component analysis (PCA)

PCA plots are used here to visualise data, especially the differences between experimental conditions or detect batch effects. The principal components are variables underlying the data set that explain the maximum amount of data variance with as few principal components as possible, with the aim to visualise multi-dimensional expression data in a two-dimensional plot. To create a PCA plot, the matrix of normalised counts created in DESeq2 was used. A regularised log transformation was performed on the data matrix. This has a variance stabilising effect, especially helping to minimize the differences between samples for rows with small counts. DESeq2 then provided a function to create the PCA plot based on the transformed data (Love et al., 2014).

### 2.4.7 Heatmaps

The R package "pheatmaps" (V1.0.8) was used to draw heatmaps (Kolde, 2015). This software uses count data after regularised logarithmic transformation (performed by DESeq2) as input to draw heatmaps of a specified subset of genes. To produce a heatmap, the program then calculates a Z-score, i.e. the number of standard deviations a data point is from the mean, which allows for better scaling across all samples than for example plotting the log-fold change. K-means clustering is used by pheatmaps.

### 2.4.8 Gene Ontology (GO) term enrichment

To perform GO term enrichment analysis on the sets of differentially expressed genes, topGO (Alexa et al., 2006) was used. GO terms provide a hierarchical structure to classify genes according to their molecular function, localisation and the biological process in which they are involved (GO Consortium, 2004). The analysis of GO terms in this thesis was restricted to those in the categoriy "Biological Process". Genes significantly up or down-regulated (usually with an adjusted p-value of $<0.01$ ) in a particular condition were used as input for topGO and GO terms were considered significantly enriched if their p-value was $<0.05$.

### 2.4.9 InterProScan \& Pfam enrichment

The program InterProScan 5.0.7 (Quevillon et al., 2005; Zdobnov \& Apweiler, 2001) was used to identify conserved protein domains. The sequences of all annotated Schistosoma mansoni proteins were used as input. This produces a list of all matches between the provided sequences and annotated protein domains, including Pfam matches. From the output, all Pfam (Finn et al., 2014) domains were used that were identified with high confidence ( $p$-value $<0.01$ ). Duplicate domains were also removed, i.e. those that occurred more than once in a protein, to prevent the enrichment statistics to be skewed by such proteins. Furthermore, all domains, only found in a single $S$. mansoni protein were removed because no meaningful enrichment analysis could be performed on them. In total 1479 different domains in 6835 proteins were kept for further analysis.

Using a custom python script this information was combined with the results of differential expression analysis from DESeq2 to determine if the differentially expressed genes (DEGs) were enriched for proteins containing particular domains. The script created a table as output that was opened using Microsoft Excel to calculate if a domain was significantly more or less abundant than expected by change using a two-sided hypergeometric test. Domains were accepted to be significantly enriched if p < 0.05 and if the domain in question was found more frequently than the average domain. This resulted in excluding domains which were actually depleted in a sample, rather than enriched. For examples it might exclude the egg shell synthesis domains from being shown as significantly depleted in male worms; however, this domains would be shown as significantly enriched in female worms.

### 2.4.10 KEGG pathway enrichment

The Kyoto Encyclopedia of Genes and Genomes (KEGG) database online resource (Kanehisa \& Goto, 2000) was used to provide pathway information, as they have reference pathways from hundreds of metabolic and signaling pathways. The html files of all KEGG entries of $S$. mansoni genes were downloaded and the corresponding GeneDB IDs as well as KEGG pathways associated with the gene in question were extracted from the files. Using this information, a table containing all S. mansoni genes and all pathways that the given gene belongs to was created. In total 2046 genes with KEGG pathway annotation were identified. In total genes belonging to 112 pathways were found.

After DESeq2 analysis of RNA-seq data, a python script was used to count the number of DEGs found to belong to each pathway. The script would create a table that can be opened by Microsoft Excel to calculate if the number of genes belonging to a given pathway was significantly higher than expected by chance using a two-sided hypergeometric test. Pathways were accepted to be significantly enriched if $\mathrm{p}<0.05$ and if it was found more frequently that the average pathway. As in the case of domain enrichment, pathways which were actually depleted, rather than enriched were excluded from the analysis, as they would usually be found to be significantly enriched in the other condition of the DESeq2 analysis.

For example, in Chapter 5, in a comparison of female worms from SS and MS infections, 2726 DEGs were identified, of which 787 were up-regulated in MS females. Of the 787 DEGs in MS females, 365 were annotated as members of a KEGG pathway. Across all pathways, about $37 \%$ of annotated genes were upregulated in MS females, including 75 of 110 (68\%) genes associated with the Ribosome KEGG pathway (smm03010); a greater proportion of DEGs in this pathway are upregulated than expected by chance as was determined using a hypergeometric test, demonstrating that the genes up-regulated in MS females are significantly enriched with ribosom related genes ( $p=8.47 \mathrm{E}-12$ ).

On the other hand, in SS females, 1939 DEGs were identified, but none of the 110 ribosome-associated genes were found to be up-regulated. On average only about $14 \%$ of the genes associated with KEGG pathways were up-regulated in SS females. As a result, expression of ribosomal genes was also found to be
significantly different from the expected (14\%) DEGs in SS females (p-value $=$ 6.67E-08). However, in this case the proportion of DEGs in the Ribosome pathway is lower than expected by change (it is in fact 0 ). As a result the hypergeometric test demonstrated that the genes up-regulated in SS females are significantly depleted of ribosome related genes.

Because the depletion of a pathway in one sample usually mirrored the enrichment of that same pathway in the other sample in a gene expression comparison, only significantly enriched pathways were considered in the results of the following chapters.

### 2.4.11 Cluster analysis of RNA-Seq data

Two R packages were used to cluster RNA-Seq data by the pattern of gene expression across different samples: MBCluster (Si et al., 2013) and Kohonen (Wehrens, 2015). The MBCluster analysis was performed in R using counts normalised for library size as input; the size factors used to correct for library size were provided by DESeq2 (see 2.4.4). MBCluster models the data to follow a negative binomial distribution and uses an Expectation-Maximisation algorithm to estimate model parameters and divides genes into groups, or clusters, with similar expression patters across the different samples. Importantly, MBCluster was designed to cluster genes according to their expression profile (i.e. the relative changes in expression) but not absolute expression levels. Kohonen is also an $R$ package used to group genes by their expression across different samples. Unlike MBCluster, Kohonen is based on an heuristic method designed to produce self-organising maps (SOM), a type of artificial neural network, from
data sets using unsupervised learning. It uses data that has undergone regularised logarithimic transformation as input (provided by DESeq2). The data was then processed to have a mean expression of zero for each gene. This allows Kohonen to cluster the genes by the magnitude of changes in their expression, not absolute expression. Kohonen initially uses a random distribution of data point across the map, but then trains the map until it reaches an optimal distribution of data point across the SOM.

### 2.4.12 Gene models \& annotation

The annotation of DEGs was checked using a combination of BLAST, against gene sequences of model organisms, as well as Pfam to identify relevant domains in the predicted protein sequences. For Chapters 3 and 4 a list of putative apoptosis-related genes was compiled. These genes were identified from the literature (Lee et al., 2011; Lee et al., 2014; Peng et al., 2010), as well as by using BLAST to identify S. mansoni homologues of genes annotated in the KEGG database as apoptosis-related genes. Especially Homo sapiens and Caenorhabditis elegans gene sequences were used to BLAST against all S. mansoni genes on the GeneDB database. An e-value of $1.00 \mathrm{E}-05$ was used as significance cut-off. Additionally Pfam was used to confirm the presence of conserved domains, important to the function of protein product. Using the Artemis Comparison Tool, RNA-Seq evidence was used to improve predicted gene models of the apoptosis-related genes. Using the RNA-Seq data mapped by Tophat2, both exons that had not been previously annotated, as well as the exon-intron boundaries were checked and any changes submitted to GeneDB.

### 2.5 Scanning Electron Microscopy

Freshly perfused worms were washed in PBS and then fixed in $2.5 \%$ glutaraldehyde and 2\% Paraformaldehyde in PBS for 1 h . Specimens were then prepared for scanning electron microscopy using the osmium tetroxide/thiocarbohydrazide method (Malick \& Wilson, 1975). The following steps were performed by Dave Goulding, WTSI, Hinxton. The samples were rinsed in 0.1 M sodium cacodylate buffer and then alternated between incubation in $1 \%$ osmium tetroxide and incubation in $1 \%$ thiocarbohydrazide for a total of 5 incubations. Following these incubations the specimens were dehydrated in an ethanol series (30\%, 50\%, 70\%, $90 \%$ and $100 \%$ ). Then a critical point drying was performed in a Bal-Tec CPD030 and specimens were mounted on aluminium stubs with silver dag. Finally samples were coated with a 2 nm gold layer in a Bal-Tec SCD050 and examined in a Hitachi S-4800 scanning electron microscope.

Chapter 3

Transcriptome analysis of male and female
S. mansoni during intra-mammalian development

### 3.1 Introduction

The aim of this Chapter is to explore the transcriptome changes that occur during the development of male and female schistosomes inside the mammalian host, with a particular emphasis on sexual maturation taking place after pairing. As discussed in detail in the introduction to this thesis, female maturation is dependent on stimulation by a male partner. Here, I examined the transcriptomes of female and male worms in the days leading up to pairing as well as the weeks following pairing. In particular, I wanted to explore how the male and female transcriptomes change over time and how the gene expression of worms from mixed sex (MS) infections differs from that of single sex (SS) infections.

In this Chapter, a variety of functional genomic tools and databases were used to investigate differentially expressed genes. Using a combination of different tools, such as GO terms, KEGG pathway and Pfam domain enrichment, I was able to get a more thorough understanding of the processes taking place in the developing worms.

While many previous studies on pairing-induced changes in gene expression used microarrays (Fitzpatrick \& Hoffmann, 2006; Leutner et al., 2013), a recent study used RNA-Seq (Sun et al., 2014). An analysis of female worms at 18 and 23 d.p.i. from both SS and MS infections was performed, to study female gene expression in the presence or absence of male worms, but also the changes that take place between the two time points. Although almost 3000 differentially expressed genes (DEGs) were identified in some of their comparisons, their
approach left room for improvement. Their method of RNA-Seq relied on sequencing tags, which are short, 17 base-pair sub-region of a whole cDNA sequence. As result the tags do not cover transcripts along their entire lengths which can make gene expression less quantifiable (Wang et al., 2009). More importantly, the authors did not sequence any biological replicates for any of their samples for their conditions, although this has now become standard practice as it allows for a more robust statistical analysis by making it possible for the variation within treatment groups to be measured accurately (Schurch et al., 2016). This is because variability between biological replicates is often higher than expected, so without biological replicates real differences in expression between treatment groups cannot be reliably distinguished from random fluctuations in expression (Schurch et al., 2016). The method of determining differentially expressed genes is not described in detail in the methods (the authors refer to "a rigorous algorithm [that] was adopted to screen genes that were differentially expressed between samples"), making it difficult to replicate their analysis and their results (Sun et al., 2014). Finally, the authors performed a pathway analysis using th identified DEGs (Sun et al., 2014). However, in their analysis Sun et al. (2014) did not evaluate the proportion of genes that were differentially expressed in each pathway and therefore did not examine the statistical significance of the up- or down-regulated pathways that they reported. For example, Sun et al. (2014) report that "pathways, such as cell adhesion molecules (CAMs), ribosome biogenesis in eukaryotes, the Notch signalling pathway" were up-regulated. However, it is not clear if what percentage of genes of a particular pathway were differentially expressed. A low proportion of DEGs
in a pathway could be the result of random chance, whereas a larger proportion could give greater conficdence in the result.

Another study examining the development of $S$. mansoni from cercaria to adult worm (Picard et al., 2016). However, the results were limited by the fact that female specimens did not experience pairing and thus did not commence sexual maturation over the course of the experiment (Picard et al., 2016). Most recently, Wang et al. (2017) published a RNA-seq time course of the intramammalian development of male and female S. japonicum from 14 to 28 d.p.i.. The results suggested that biogenic amines and insect-hormone-like receptors play crucial roles in male-female signalling and sexual maturation of ovaries and vitelline glands in female worms (see Chapter 1.6.2). Using RNAi targeted at the insect-hormone-like receptor, the authors provided evidence of a role of the insect-hormone-like receptor in the development of these reproductive tissues (Wang et al., 2017). However, no RNAi results were reported for the AADC gene involved in the production of amines. The authors only analysed the transcriptomes of worms from MS infections. This makes it more difficult to distinguish the changes in expression linked to pairing from those that occur independently of pairing as the worms develop without the opposite sex. Notably, the development of S. japonicum as described by Wang et al. (2017) appears to be accelerated when compared to $S$. mansoni (see Chapter 1.2.1), as the worms were observed to pair and reach sexual maturity consistently earlier than in equivalent studies on S. mansoni (Biolchini et al, 2006). Differences in the speed of development, even between strains of the same species of schistosome, have been reported before (Hsü et al., 1962).

In my experiment, male and female $S$. mansoni from MS and SS infections were collected and processed for RNA-Seq at six time points: days $18,21,28,35,38$ and 49 d.p.i.. My analysis included not just the transcriptome changes taking place in female worms but also those of male worms. Robust statistical analyses were used to determine differentially expressed genes and pathway enrichment analysis. Additional bioinformatics tools were used, including Pfam domain analysis, GO terms and cluster analysis (see Chapter 2.4), to infer the potential roles of differentially expressed genes in the development and sexual maturation. Finally, I used whole mount in situ hybridisation and RNAi to characterised two genes found to be involved in female sexual maturity. This was done to explore the site of expression as well as the function of these genes in $S$. mansoni using respectively.

### 3.2 Results

### 3.2.1 Egg laying

The livers of infected mice were examined for the presence of $S$. mansoni eggs (Figure 3.1), as described in Chapter 2.1.3. Schistosome eggs were found exclusively in livers of mice infected with MS parasites at 35 and 38 d.p.i. As expected, eggs were not observed in the livers of mice with the SS infections. Although paired worms were recovered at 28 d.p.i. from mice with MS infections, no eggs could be recovered from the livers of these mice. Since pairing is thought to take place from around 28 d.p.i. (Basch, 1991) most female worms would not
started egg laying at this time point. However, a very low egg count could have gone undetected.

no eggs in liver
eggs discovered in liver
Figure 3.1: Eggs were only detected in the livers of mice with mixed sex infections. Single sex infections with male or female worms were found not to yield eggs at any time point, where as mixed sex infections were found to yield eggs from 35 d.p.i., but not 21 and 28 d.p.i. At 18 and 49 d.p.i. no mixed sex infection were available ("-").

### 3.2.2 Sequencing and sample clustering

The RNA-Seq data was prepared as described in Chapter 2.4, yielding over 20 million reads for each of the 70 samples (see Appendix A. 1 for details). On average, $79 \%$ of the reads could be mapped to the $S$. mansoni genome (v5.2) (Appendix A.1), with the remainder mostly comprising PCR artefacts, especially primer dimers, created during the amplification of the sequencing library. Samples were then analysed using DESeq2. First, a principal component analysis (PCA) plot (Figure 3.2) was created of all samples. This gives a simplified overview of how developing male and female worms differ at the transcriptome level across the time course from 18 to 49 d.p.i. in MS and SS infections. While male worms from SS and MS infections develop at a similar rate, females from SS infections are known to become arrested at an early developmental stage (Popiel, 1986). This was reflected at the transcriptome level by the PCA plot as well as the following differential expression analysis (see Chapters 3.2.4 and
3.2.5). From 21 d.p.i. the gene expression of SS females remained almost unchanged, developmentally arrested, and most similar to MS females at 21 d.p.i. Females from MS infections became very distinct from all other samples from 28 to 38 d.p.i. at the transcriptome level.

Figure 3.2: Samples group into male, as well as mixed and single sex female clusters. Principle Component Analysis (PCA) plot of gene expression in developing male and female S.mansoni from single sex (SS) and mixed sex (MS) infections at 18-49 days post infection (d.p.i.) PC1 explains $57 \%$ of the variance observed in the data set and broadly correlates with female sexual maturity over time, whereas PC2 explains only $17 \%$ of the variance and broadly correlates to male maturity. Together $74 \%$ of variance across the data set is captured by the first two principal components.

These findings reflected that female sexual development depends on pairing with a male whereas male maturation is largely independent of the female, as has been noted in the literature (Basch, 1991). In this context, it was also interesting to note that female worms from MS and SS infections were transcriptomically very similar at 21 d.p.i., but diverged significantly after 28 d.p.i., when pairing is thought to take place (Basch, 1991). It should also be noted that male and female samples from MS infections separate very well at all available time points (it should be noted that the males and females from SS infections at 18 d.p.i. did not separate). This shows that males and females were correctly identified even at 21 d.p.i. using morphological differences outlined by Basch (1991).

### 3.2.3 Gender-specific gene expression

During their intra-mammalian development, male and female worms grow from morphologically similar immature stages to distinct male and female worms that are usually reproductively active by 35 d.p.i. (Biolchini et al., 2006). Pearce and Huang (2015) suggested that the sexual dimorphism of male and female worms can be explained by adaptations for different biological roles. This allows for a unique co-dependency that maximises egg production. The male, for instance, is responsible for moving the pair to the site of oviposition (Basch, 1991).

Figure 3.3: The male and female transcriptome becomes increasingly different, especially from 28 to 35 days post infection. A) Number of differentially expressed genes between male and female worms from mixed sex infections at 21 to 38 days post infection. Genes were considered to be differentially expressed if the adjusted $p$-value of $<0.01$ and fold-change $>2$. B) Log ratio vs mean (MA) plots of pair-wise comparisons of gene expression in male and female worms from MS infections from 21 to 38 d.p.i. Genes with an adjusted p-value of $<0.01$ are highlighted in red, the others are grey. The black lines represent the fold change cut-off (log-fold change $= \pm 1$ ). Triangles indicate genes outside the boundaries of the plots; like other genes, they are red if they are statistically significant, grey if they are not.

In order to identify genes differentially expressed between male and female worms from MS infections at 21, 28, 35 and 38 d.p.i. DESeq2 was used. The threshold for differential expression was an adjusted p-value of $<0.01$ and a fold-change in expression > 2 throughout this Chapter. Pairwise comparisons of males and females at each time point showed that there was an increase from 38 DEGs at 21 d.p.i. to over 3600 DEGs at 38 d.p.i. (of 10828 genes in total). The biggest absolute increase occurred from 28 to 35 d.p.i., approximately $1270 \%$ (Figure 3.3), as males and females diverge transcriptomically. These changes are responsible for the development of sex-specific features and the increasing proportion of reproductive tissues such as ovaries and vitellaria in female worms.

At 21 d.p.i., male and female worms from MS infections were very similar at the transcriptome level. Of the 38 DEGs (see Figure 3.3a), 22 were up-regulated in females and 16 in males (see Appendix A. 2 and A. 3 for full lists of DEGs). In female worms several genes involved in cell division and cell fate determination
could be identified (Table 3.1). First, the gene coding for MutS, a protein implicated in mismatch DNA repair, was up-regulated (Table 3.1). Second, female worms express higher levels of the gene coding for Delta-like protein (Table 3.1), which is a ligand of Notch receptors involved in cell fate determination (Zhou et al., 2010). Third, a gene coding for a single minded-like protein was up-regulated in female worms (Table 3.1). In Drosophila, single minded is required for the proper development of midline cells (Nambu et al.,1991). At 21 d.p.i. both male and female worms are in the process of developing their reproductive organs (Biolchini et al., 2006) as well as their gut (Basch, 1991) and these gene may be involved in regulating these processes.

| Gene ID | Product | Fold Change | Adjusted p-value |
| :--- | :--- | ---: | ---: |
| Smp_213480 | MutS protein | 6.54 | $9.36 \mathrm{E}-06$ |
| Smp_178780 | Single minded | 4.78 | 0.00160 |
| Smp_141250 | Jagged 1 | 2.59 | 0.00874 |

Table 3.1: Cell division related genes up-regulated in females from mixed sex infections at 21 days post infection. Fold changes are relative to expression in male worms from mixed sex infections at 21 d.p.i. (see Appendix A. 3 for full list). The $p$-value has been adjusted for multiple hypothesis testing.

In males, two nervous system related genes were found to be up-regulated at 21 d.p.i. (Appendix A.3). One of the two genes encoded a sodium chloride dependent neurotransmitter (Smp_160360, 3.54-fold change, adjusted p-value $=3.36 \mathrm{E}-07$ ). The other encoded a neuropeptide receptor (Smp_133550, 2.0 -fold change, adjusted p-value $=0.0067$ ). Collins et al. (2010) showed that neuropeptide Y is involved in the development and maintenance of the germline in planarians and identified peptide homologues in $S$. mansoni. This evidence suggests the differential use of neuropeptide receptors in male and female $S$. mansoni in the
mammalian stage of their life cycle. Smp_133550 remains significantly upregulated in males at 38 d.p.i. ( 7.1 -fold change, adjusted p-value $=2.79 \mathrm{E}-21$ ) (Appendix A.4). Together, the differentially expressed genes suggest that the development of male and female worms including that of the nervous system has begun to diverge by 21 d.p.i., priming the otherwise transcriptomically very similar males and females for their sex-specific development.

At 38 d.p.i. approximately $33.4 \%$ (3616) of all genes were found to be differentially transcribed (Figure 3.3), revealing the extraordinary degree to which mature females from MS infections differ from their male counterparts. 1377 of the 3616 DEGs were up-regulated in females (Figure 3.3). Among the female DEGs were several encoding well known fertility-associated proteins including female specific protein 800 (fs800) and other trematode egg shell synthesis domain containing proteins, two tyrosinases and an extracellular superoxide dismutase all of which were at least 80 -fold up-regulated compared to male worms (adjusted p-value $<4.00 \mathrm{E}-22$ ) (Appendix A.5). Another gene upregulated in females encodes a homologue of the human TNF receptor associated protein 1 (TRAP1; Smp_155740) (Appendix A.5).

At 38 d.p.i., MS male worms express 2239 genes at significantly higher levels than females (Figure 3.3). A selection of 29 genes pre-dominantly expressed in males was identified in the literature (Fitzpatrick et al., 2005; Piao et al., 2011) and tested for male-biased expression. All 29 genes were found to be differentially expressed (Table 3.2), including genes coding for collagen, calpain and musculature related proteins.

| Gene ID | Product | Fold change | Adjusted p-value |
| :--- | :--- | ---: | ---: |
| Smp_006860 | PDZ \& LIM protein | 4.66 | $9.42 \mathrm{E}-23$ |
| Smp_022340 | PDZ \& LIM protein | 5.83 | $6.54 \mathrm{E}-22$ |
| Smp_166920 | PDZ \& LIM protein | 7.50 | $8.16 \mathrm{E}-22$ |
| Smp_164590 | Fibrillar collagen $\alpha$ | 4.65 | $8.03 \mathrm{E}-12$ |
| Smp_123830 | Collagen $\alpha$ (xi) chain | 4.14 | $6.81 \mathrm{E}-12$ |
| Smp_196840 | Collagen $\alpha$ 1(II) chain | 2.59 | $7.50 \mathrm{E}-09$ |
| Smp_170340 | Collagen $\alpha$ 1(IV) chain | 5.68 | $2.01 \mathrm{E}-07$ |
| Smp_156770 | Tegumental antigen Sm15 | 7.26 | $5.12 \mathrm{E}-14$ |
| Smp_179810 | Tegumental antigen Sm8 | 5.06 | $8.86 \mathrm{E}-15$ |
| Smp_214180 | Calpain | 3.48 | $7.16 \mathrm{E}-18$ |
| Smp_214190 | Calpain | 3.03 | $2.08 \mathrm{E}-21$ |

| Smp_059170 | Troponin | 7.43 | $1.07 \mathrm{E}-22$ |
| Smp_174520 | Dynein light chain | 4.08 | 0.0031 |
| Smp_176300 | Dynein heavy chain | 2.34 | $1.13 \mathrm{E}-06$ |
| Smp_212280 | Dynein heavy chain | 3.11 | $1.17 \mathrm{E}-13$ |
| Smp_140500 | Paramyosin | 2.13 | 0.0003 |
| Smp_021920 | Paramyosin | 6.85 | $9.62 \mathrm{E}-08$ |

Table 3.2: Differential expression analysis confirmed male-biased expression patterns of known male-specific genes from the literature (Fitzpatrick et al., 2005; Piao et al., 2011). This was a comparison of male and female worms from mixed sex infections at 38 days post infection. Fold changes are provided relative to female expression; all genes in this table were upregulated in male worms. The $p$-value has been adjusted for multiple hypothesis testing.

As in MS males at 21 d.p.i., the neuropeptide receptor (Smp_133550) was found to be up-regulated in MS males at 38 d.p.i. (fold change $=7.1$, adjusted p -value $=$ 2.79E-21). Additionally, another G-protein coupled receptor (Smp_170020, 9.1fold change, adjusted p -value $=2.54 \mathrm{E}-30$ ) with homology to neuropeptide receptors was found to be up-regulated in the male worms (Table 3.3). Overall, a high proportion (13 out of 16) of neurotransmitter-gated ion channels (identified by their PFAM domain annotation) were significantly up-regulated in male worms compared to female worms (Table 3.3). These include three
glutamate-gated chloride channel subunits (2, 3 and 4) (Smp_015630, Smp_104890 and Smp_099500), seven out of eight nicotinic acetylcholine receptors and receptor subunits (Smp_031680, Smp_012000, Smp_132070, Smp_180570, Smp_139330, Smp_157790 and Smp_176310), as well as an acetylcholine receptor subunit $\alpha$ (Smp_101990), a neural acetylcholine receptor subunit $\alpha 4$ (Smp_037960) and a glycine receptor subunit $\beta$ (Smp_096480) (Table 3.3). Of the remaining three neurotransmitter receptors identified in the S. mansoni genome, one is up-regulated in females (Smp_142690), while expression of the remaining two could not be detected at this stage of the life cycle (Smp_175110, Smp_197600) (Table 3.3). This striking enrichment in neurotransmitter receptor mRNA expression in male worms over female worms raises questions on the role of these proteins in the male reproductive process. When comparing expression of these 13 genes in males to female worms from SS infections, no such enrichment is found (Appendix A.6); only two of the genes, Smp_104890 and Smp_101990, are still expressed at significantly higher levels in male worms than in the immature females (Appendix A.6). This suggests that the relative abundance of different tissue types is responsible for the up-regulation of neurotransmitter receptor genes in male worms. The large proportion of ovarian and particularly vitellarian cells in mature females as well as the relatively lower proportion of muscle (Loker \& Brant, 2006) may be responsible for the lower relative expression of neurotransmitter genes in whole females. In contrast, immature female are more male-like than mature females at the transcriptome level, due to the lack of developed reproductive organs.

| Gene ID | Product | Average read count | Fold change | Adjusted p-value |
| :---: | :---: | :---: | :---: | :---: |
| Smp_015630 | Glutamate-gated chloride channel subunit | 353.74 | 4.61 | 1.23E-06 |
| Smp_104890 | Glutamate-gated chloride channel subunit | 244.18 | 6.03 | 7.84E-24 |

Table 3.3: Neurotransmitter-gated ion channels are largely up-regulated in male worms. The differential expression analysis compares male and female worms from mixed sex infections at 38 days post infection. Average read counts are a measure of absolute expression across all samples, and fold changes are provided relative to female expression (fold changes > 1 indicate up-regulation in males). If no expression was measured, fold change and $p$-value are marked as $\mathrm{N} / \mathrm{A}$. The $p$-value has been adjusted for multiple hypothesis testing.

To better understand what biological processes the DEGs play a role in in females and males I made use of the KEGG database and performed a pathway enrichment analysis to identify pathways with significantly more DEGs than expected by chance. At 38 d.p.i., the DEGs upregulated in MS females were found to be enriched for 13 pathways involved in DNA replication and protein synthesis (Table 3.4), reflecting the proliferation of ovarian and especially vitellarian cells to drive egg production. In contrast, several lipid-metabolic pathways, developmental signalling pathways and pathways involved in
endocytosis were significantly enriched in males (see Table 3.5). Amongst these, is the TGF- $\beta$ pathway that has been implicated in the male-female interaction and the stimulation of female fertility (LoVerde et al., 2009) (Table 3.5). Another up-regulated pathway is phosphatidylinositol signalling (smm04070, p -value $=$ 0.020 ) (Table 3.5). It has been proposed that female fertility is supported by lipid transfer from the male to the female (Popiel \& Basch, 1986). Several lipid metabolism-related pathways were indeed significantly enriched in the DEGs upregulated in males at 38 d.p.i., including glycerolipid and glycerophospholipid metabolism (smm00564, p-value $=0.00019 ;$ smm00561, p -value $=0.00059$ ) as well as ether lipid metabolism (smm00565, p-value $=0.0082$ ) (Table 3.5). However, this could also simply reflect a higher rate of tegument turnover in male worms, which have a thicker tegument as well as a larger surface area, due to their flattened morphology.

Table 3.5 Male worms upregulated KEGG pathways involved in cellular metabolism and various signalling pathways.At 38 days post infection, genes upregulated in males from mixed sex infections were enriched in 19 KEGG pathways. "Total genes" is the number of genes in the given pathway. "DEGs" provides the number of differentially expressed genes in that pathway. "Expected" provides the number of genes expected by chance to be differentially expressed in each pathway.

### 3.2.4 Male development

In male worms, the greatest difference in gene expression was found between 18 and 21 d.p.i. (1858 DEGs in total) (Figure 3.4), suggesting that this was when most of the male-specific developmental changes took place. The number of DEGs dropped sharply after that time, to 130 (21 vs 28), 59 ( 28 vs 35 ) and finally 17 DEGs (35 vs 38), (Figure 3.4). Below, some of the results of the differential expression analysis are discussed in detail.

B)

18 d.p.i. compared to 21 d.p.i.

28 d.p.i. compared to 35 d.p.i.

mean expression

21 d.p.i. compared to 28 d.p.i.

35 d.p.i. compared to 38 d.p.i.

mean expression

Figure 3.4: The largest number of differentially expressed genes was found between 18 and 21 days post infection (d.p.i.) in developing male worms. A) This plot provides the number of differentially expressed genes found by pairwise comparisons of males from mixed sex infections of different time points. B) Log ratio vs mean (MA) plots showing the mean expression and log-fold change of each pair-wise comparison. Genes marked as red dots have been assigned an adjusted p -value of $<0.01$, the other are grey. Black lines represent the fold change cut-off (log-fold change $= \pm 1$ ). Triangles indicate genes outside the boundaries of the plots; like other genes, they are red if they are statistically significant, grey if they are not.

## Cytochrome P450-dependent drug metabolism

Praziquantel is currently the main drug to treat schistosomiasis, especially as part of mass treatment programs in endemic areas (Crellen et al., 2016). However, immature worms are known to be less sensitive to praziquantel, making it difficult to clear an infection completely and stop the parasite life cycle in endemic areas (Sabah et al., 1986; Vimieiro et al., 2013). At 18 d.p.i., three out of four genes belonging to the cytochrome P450 dependent drug metabolism pathway were found to be up-regulated in males worms compared to male worms at 21 d.p.i. (Appendix A.7). The relatively high expression of genes involved in cytochrome P450-dependent drug metabolism at 18 d.p.i. may be the reason why immature worms are less susceptible to praziquantel. A Glutathione S transferase (GST) was not only up-regulated in males at 18 d.p.i. compared to males at 21 d.p.i. (Smp_024010, 5.1 -fold change, adjusted p-value $=4.50 \mathrm{E}-05$ ) (Appendix A.8), but also compared to males at 38 d.p.i. (21.9-fold change, adjusted p -value $=1.34 \mathrm{E}-14$ ) (Appendix A.8). The same gene was also upregulated in female worms at 18 compared to 38 d.p.i. (18.2-fold change, adjusted $p$-value $=1.30 \mathrm{E}-11)($ Appendix A. 8$)$.

## Regulation of cell division in the testes

Compared to 21 d.p.i., the gene coding for the cell cycle regulator Cdc25 (Smp_152200, 6.0-fold change, adjusted p-value $=0.00061$ ) was up-regulated at 28 d.p.i. in male worms, as was follistatin (Smp_123300, 2.3 -fold change, adjusted p -value $=0.00027$ ) (Appendix A.9). Follistatin is also associated with the proliferation of spermatocytes and was also found to be down-regulated from 28 to 35 d.p.i. (2.4-fold change, adjusted p-value $=0.00082$ ) (Appendix A.10). Leutner et al. (2013) demonstrated that paired male worms express lower levels of follistatin than unpaired males. The down-regulation of the gene encoding follistatin in MS males at 35 d.p.i. compared to those at 28 d.p.i. is probably related to this observation (Appendix A.10). From 21 to 28 d.p.i., a gene encoding the homologue of basonuclin 2 (Smp_138350, 5.4-fold change, adjusted p -value $=1.86 \mathrm{E}-05$ ) was up-regulated in male worms from mixed sex infections (Appendix A.16).

## Aromatic-L-amino acid decarboxylase

Wang et al. (2017) hypothesised that the AADC gene, which they found to be expressed in S. japonicum males during mating (see Chapter 1.6.2), was responsible for inducing female sexual maturity. The AADC gene was also found to be up-regulated in male S. mansoni. The S. mansoni gene (Smp_135230) was significantly up-regulated in male worms at 38 d.p.i. compared to males at 18 d.p.i. (8.50-fold change, adjusted p -value $=2.26 \mathrm{E}-06$ ) (Appendix A.11). Additionally, it was found to be significantly up-regulated in male worms from MS infections compared to males in SS infections at 35 d.p.i. (8.39-fold change, adjusted $p$-value $=1.23 \mathrm{E}-03$ ) and 38 d.p.i. (5.33-fold change, adjusted $p$-value $=$
1.99E-03), falling just short of the significance threshold (adjusted p-value < $0.01)$ at 28 d.p.i. $(2.32$-fold change, adjusted $p$-value $=0.0359)($ Appendix A.11) . The lack of expression in males from SS infections as well as the confirmation of expression in mature MS males (here in S. mansoni) adds further weight to the hypothesis of AADC being involved the stimulation of female fertility in schistosomes.

### 3.2.5 Female development

Pairing is thought to commence between three and four weeks post infection, allowing female worms to reach sexual maturity around five weeks post infection (Biolchini et al. 2006). Accordingly, the greatest difference in gene expression in MS female worms was found between 28 and 35 d.p.i. (1545 DEGs) (Figure 3.5). By comparison, there were only 300 DEGs between 18 and 21 d.p.i., 385 between 21 and 28 d.p.i. and 29 between 35 and 38 d.p.i. (Figure 3.5).

Figure 3.5: The largest number of differentially expressed genes (DEGs) was found between 28 and 35 days post (d.p.i.) infection in female worms from mixed sex infections. A) DEGs found by pair-wise comparisons of females from mixed sex infections at different time points. B) Log ratio vs mean (MA) plots show the mean expression and log-fold change of each pair-wise comparison. Genes marked as red dots have been assigned an adjusted $p$-value of $<0.01$, the others are grey. Black lines represent the fold change cut-off (logfold change $= \pm 1$ ). Triangles indicate genes outside the boundaries of the plots; like other genes, they are red if they are statistically significant, grey if they are not.

## Egg production related genes

During the maturation of paired female schistosomes, many fertility related genes are known to become up-regulated (Fitzpatrick \& Hoffmann, 2006). This is largely due to the growth and maturation of the reproductive organs including the ovaries and the vitellarium (Fitzpatrick \& Hoffmann, 2006). Many of the significantly up-regulated genes were also found in the comparison of male and female worms (Chapter 3.2.3). In this comparison of females from different time points, the most notable up-regulation of fertility-related genes occurred between days 21 and 28, where 266 DEGs were found to become up-regulated (Figure 3.5). The DEGs included all genes encoding trematode egg shell synthesis domains, a tyrosinase (Smp_050270), and the extracellular superoxide dismutase (Smp_095980) (Appendix A.12). Furthermore, two tetraspanins were up-regulated, CD63 antigen (Smp_173150) and a CD63 receptor (Smp_155310) (Appendix A.12). Although CD63 antigen is expressed in mature females, its function remains unclear (Cogswell et al., 2012). At 38 d.p.i., females from MS infections expressed the CD63 receptor and antigen, at 191-fold (adjusted pvalue $=5.98 \mathrm{E}-30$ ) and 39 -fold (adjusted p -value $=1.62 \mathrm{E}-42$ ) higher levels
respectively, than females from SS infections (Appendix A.13). This made them the $21^{\text {st }}$ and $51^{\text {st }}$ of the most differentially expressed genes, the majority of which are thought to be expressed in the vitellarian tissue. Together the DEGs summarised in this paragraph confirmed that female schistosomes from MS infections have not only begun to pair by 28 d.p.i. but also that females have started to develop their reproductive organs at that time. As others recently observed (Biolchini et al., 2006), it appears that pairing takes pace somewhat earlier than reported by Basch (1991). These genes became further up-regulated at 35 d.p.i. and 38 d.p.i. and were consistently expressed at significantly higher levels in females from MS infections rather than SS infections (see Chapter 3.2.8).

## Ovary-specific gene expression

While the most differentially expressed genes up-regulated in mature females are thought to be largely expressed in the vitellaria [for example Fitzpatrick et al. (2007), Fitzpatrick \& Hoffmann (2006), Köster et al. (1988)], at 21 d.p.i. (compared to 18 d.p.i.), a least two of the up-regulated genes probably play an important role in the ovaries of mature females. The first encoded a homologue of human sperm associated antigen (Smp_001160, 2.2-fold change, adjusted pvalue $=2.08 \mathrm{E}-05)($ Appendix A.14), which plays a role in fertility in mammals (Lin et al., 2001). The other encoded boule (Smp_144860, 6.6 -fold change, adjusted p -value $=6.34 \mathrm{E}-05$ ) (Appendix A.14), a conserved transcription factor found in most animals. Amongst others, it has been shown to regulate male and female gametogenesis in the flatworm Macrostomum ligano (Kuales et al., 2011). In S. mansoni, boule was also expressed specifically in the gonads (Chapter 5.2).

## WNT signalling

At 18 d.p.i., females express two wht family genes (Smp_196930, 2.5 -fold change, adjusted p-value $=0.0027 ;$ Smp_167140, 3.1 -fold change, adjusted p-value $=$ 0.0067 ) that became down-regulated at at 21 d.p.i. (Appendix A.15) Additionally, a gene (Smp_062560, 2.2 -fold change, adjusted p-value $=0.0067$ ) homologous to a Secreted frizzled-related protein 2, a regulator of the Wnt pathway, was upregulated (Appendix A.15) Frizzled proteins are G-protein coupled receptors that regulate the Wnt signalling pathway (Nusse, 2009). Up-regulation of these three genes suggests, that the Wnt signalling pathway is more active during the earlier parts of their development, where it could regulate the formation of a body axis, cell fate and cell proliferation.

## Differential expression of transcription factors

Across this RNA-seq time course, many transcription factors were found to be differentially regulated. In particular a large number of genes coding for proteins regulating transcription became down-regulated at in females worms from MS infections at 28 d.p.i. when compared to 21 d.p.i. (Appendix A.17). Based on their GO term annotations, 37 transcription factor genes were identified: about a third of all the DEGs down-regulated at 28 d.p.i. (Appendix A.17). Such large-scale down-regulation of transcription factors in females from MS infections could suggest that some development processes reach their conclusion at this time. Of the 37 transcription factors, 22 were also expressed at significantly lower levels in females from SS infections at 28 d.p.i. and none were up-regulated (Appendix A.18).

Conversely, as the worms started to pair and females began to initiate the proliferation of their reproductive tissues, especially ovaries and vitellaria, another set of transcription factors was significantly up-regulated (Appendix A.19). Among the 100 most differentially expressed genes at 38 d.p.i. three genes with zinc finger domains were identified (Smp_166560, Smp_087320 and Smp_095350). All three zinc finger genes were found to be up-regulated more than 10 -fold (adjusted p-value < 9.00E-22) (Appendix A.19) and it is tempting to speculate that they play a role in regulating transcription of genes involved in female maturation.

### 3.2.6 Male time series analysis

The previous analysis of pair-wise comparisons made it apparent that differential expression of genes can be found across the time course, with more differential expression found between MS and SS females than males. Next, I wanted to define sets of genes regulated in a pairing dependent manner throughout the course of infection. To do so, I performed a likelihood ratio test to identify genes that were up- or down-regulated over the course of infection in worms from SS or MS infections but not in both infections. Based on this test, 39 genes (Table 3.6) were identified as differentially expressed in males from MS and SS infections across the time course (adjusted p-value $<0.01$ ) in the otherwise very similar male worms (Figure 3.6). These included several genes coding for proteins involved in signalling and signal transduction processes, such as the fibroblast growth factor (FGF) receptor activating protein (Smp_035730, adjusted $p$-value $=0.0053$ ) and the epidermal growth factor $(E G F)$ receptor (Smp_152680, adjusted p-value $=0.0069$ ), which were found to be expressed at
higher levels in paired males (Table 3.6). These genes are shown to be expressed in the testes in Chapter 5 of this thesis. The FGF and the EGF signalling pathways regulate cell proliferation and differentiation (Eswarakumar et al., 2005; Herbst, 2004). This suggests that paired males have a higher rate of cell proliferation in their testes, which could result in a greater number of spermatocytes being produced.

| Gene ID | Product | MS / SS | Fold change 38 d.p.i. | Average read count | Adjusted p-value |

Table 3.6: Significant genes found in the time series analysis of male worms. The "MS/SS" column reports whether expression was up-regulated in males from mixed sex or single sex infections at 38 days post infection (d.p.i.). The fold change is provided for 38 d.p.i. The average read count is a measure of absolute gene expression. The $p$-value has been adjusted for multiple hypothesis testing.

Figure 3.6: Male worms from mixed sex and single sex infections are very similar at the transcriptome levels throughout their development. Principal component analysis plot of male RNA-Seq samples. The first two principal components show $77 \%$ of the measured variance. The PC1 axis seems to broadly correlate with worm maturity. Time points indicate the nuber of days post infection (d.p.i.). Several outliers can be observed, especially at the late time points.

### 3.2.7 Female time series analysis

As for the male samples, a likelihood ratio test was used to identify pairingcontrolled genes in females and 5173 such genes were discovered (adjusted pvalue $<0.01$ ). At 38 d.p.i., 2670 of the genes were up-regulated in MS females and 2503 up-regulated in SS females. The PCA plot (Figure 3.7) shows female worms from MS and SS infection forming separate clusters from 28 d.p.i. onwards. To analyse such a large number of genes, two different clustering methods were used to identify groups of genes with similar expression patterns.

Figure 3.7: Female from mixed sex infections diverge from the single sex samples from 28 d.p.i. In this PCA plot of female RNA-Seq samples, the first two principal components capture $89 \%$ of the measured variance. Whereas paired females develop along PC1 over time, with sexual maturation contributing to 81\% of the total variation, single females change primarily along PC2 (8\%). Time points indicate the nuber of days post infection (d.p.i.).

### 3.2.8 Fertility-related genes

Having identified over 5000 pairing-regulated genes involved in females, I tried two different clustering methods, the Kohonen method (Wehrens \& Buydens, 2007) and MBCluster (Si et al., 2014) (Chapter 2.4.11), to split the genes into groups with similar patterns of expression. This was done to ensure the reproducibility of the clustering results and to define a set of putative fertilityrelated genes. Similar patterns of expression across several samples, especially
in time course experiments, can be evidence for co-expression and suggest roles in the same biological processes (Si et al., 2014). Kohonen is based on a heuristic method designed to produce self-organising maps from data sets using unsupervised learning. Self-organising maps are a two-dimensional representation of multi-dimensional data that aim to place similar data points, e.g. genes close to one another thereby forming clusters of similar genes (Wehrens \& Buydens, 2007). In contrast, MbCluster assumes the data to have a negative binomial distribution and uses an Expectation-Maximisation algorithm to estimate model parameters and cluster membership (Si et al., 2014).

For both methods, genes were divided into 16 clusters (Figures 3.8 and 3.9) as higher numbers of clusters usually resulted only in an increasing number of clusters with very small number of genes, even as low as one or two genes (data not shown). In the MBCluster results, one cluster, containing 76 genes, was characterised by the largest overall fold changes and high expression levels in MS females at 28, 35 and 38 d.p.i. (see Figure 3.8). This group of genes included two of the clusters formed by the Kohonen method, which separated the genes further based on their relative expression (see Figure 3.9). Of the two Kohonen clusters, one (Cluster 13) contained genes with particularly high expression in mature females. The 25 genes in that cluster are among the 32 most upregulated genes in paired females ranging from 540 -fold to over 45350 -fold upregulation over the time course (Appendix A.20). Together, these genes account for over $14 \%$ of the sequencing reads in the transcriptome of mature females, compared to only $0.0065 \%$ of reads in immature females (Appendix A.21). Eleven of the genes were found by InterProScan to code for a trematode eggshell
synthesis domain (Appendix A.20). Also included were genes coding for two tyrosinases (Smp_013540 \& Smp_050270) and an extracellular superoxide dismutase (Smp_095980) (Appendix A.20) all of which are known pairingregulated genes (Fitzpatrick \& Hoffmann, 2006).

Figure 3.8: Genes were divided into 16 clusters based on expression profiles. The MBCluster plots show gene expression across all female RNA-seq samples. For each gene in a cluster the $\log 2$ fold changes ( Y -axis) are plotted against the days post infection (X-axis). Samples from single sex (SS) infections have a white background; samples from mixed sex (MS) infections have a red background. The red lines represent the cluster average for each time point. The cluster of fertitliy-related genes dicussed above is contained within a red box.

Figure 3.9: Genes were divided into 16 clusters based on their expression using the Kohonen method. Left - heatmap of number of genes per cluster. Right - Average $\log _{2}$-expression of genes inside each cluster for all time points and for mixed and single sex females. Cluster 13 is on the top left in both maps. The two clusters of fertitliy-related genes dicussed in Chapter 3.2.8, Cluster 13 and 14 , are contained in red circles.

To select gene clusters that exhibit significant changes in expression over the time course, genes were filtered based on their average fold changes relative to expression in female worms at 18 d.p.i. The expression levels of seven out of the 16 clusters ( $1,4,7,9,11,13$ and 14) identified by the MBCluster method at least doubled or halved over the time course (see Figure 3.10). It showed that the fold changes in gene expression were larger in females from MS than SS infections. A GO term analysis was performed on the sets of genes contained in each of these 7 clusters, identifying a total of 72 significantly enriched unique GO terms.

Figure 3.10: The magnitude of changes in gene expression is larger in females from mixed sex than females from single sex infections. Average expression of genes in the MBCluster clusters with greater than 2-fold changes in gene expression across the female samples of the time course. All expression fold changes are measured relative to females from single sex infections at 18 days post infection (d.p.i.).

The clusters 9, 13 and 14 were found to be enriched for genes annotated with developmental GO terms such as multicellular organismal development, Wnt signalling and sex determination (Tables 3.7, 3.8 and 3.9). From 18 d.p.i. onwards expression of these genes fell in females from MS as well as SS infections (Figure 3.10). Notably, the down-regulation of these genes was more pronounced in females from MS infections than those from SS infections (Figure 3.10).

| GO term | Description | Annotated | Significant | Expected | p-value |
| :--- | :--- | ---: | ---: | ---: | ---: |

Table 3.9: Significant GO terms for the genes in cluster 14 of the MBCluster analysis. "Annotated" - total number of genes in the genome annotated with a given GO term. "Significant" - the number of genes annotated with that GO term in Cluster 14. "Expected" - the number of genes with that GO term expected by chance. The significance cut-off was $\mathrm{p}=0.01$. The GO terms are all in the "Biological Process" category.

Expression of Clusters 1, 4 and 7 increased over time in both SS and MS females. In all three the effect was greater in females from MS infections than females from SS infections (Figure 3.10). At 38 d.p.i. average expression was around 6and 3.5 -fold higher than at 18 d.p.i., compared with a 1.4 - and 2.4 -fold increase in SS females for clusters 1 and 4 respectively (Figure 3.10). Cluster 1 contained several genes with a female-biased expression, including gene coding for proteins such as ferritin (Smp_087760) (Appendix A.22), whereas cluster 4 contained several genes encoding saposins, cathepsins and a haemaglobinase, which may be related to digestive processes in mature females (Appendix A.23).

Cluster 7 expression displayed the greatest up-regulation of gene expression amongst all clusters (Figure 3.10). In MS females, expression was on average 60fold up-regulated at 38 d.p.i. relative to expression at 18 d.p.i. (Figure 3.10). This cluster contained many genes associated with female fertility, particularly egg production, such as genes encoding eggshell synthesis domain containing proteins (Smp_077900, Smp_000290, Smp_191910, Smp_000430 and Smp_077890), tyrosinases (Smp_050270 and Smp_013540), and asuperoxide dismutase (Smp_095980) (Appendix A.24). Cluster 7 was found to be significantly enriched for several GO terms. These included tyrosine metabolic process (GO:0006570, $\mathrm{p}=0.00014$ ), phenol-containing compound biosynthetic process (GO:0046189, $\mathrm{p}=0.00014$ ) and pigment biosynthetic process (GO:0046148, $\mathrm{p}=0.00128$ ) due to the presence of the two tyrosinases in this cluster (Appendix A.25). Both tyrosinases are known to be expressed predominantly in sexually mature females and are thought to catalyse the oxidation of phenolic compounds contributing to egg shell formation (Fitzpatrick et al., 2007). This process can produce free radicals and other oxidising agents (Tada, Kohno, \& Niwano, 2014). Superoxide metabolic process (GO:0006801, p $=0.020$ ) (Appendix A.25) was also overrepresented. Superoxide dismutases that are known to be expressed in female worms in a pairing dependant manner (Sun et al., 2014), are also found in this cluster and may serve to protect the female reproductive tissues from oxidative stress. Other up-regulated genes included genes coding for a protein kinase as well as the tetraspanin CD63 receptor (Smp_155310) and a tetraspanin CD63 antigen (Smp_173150) (Appendix A.24).

The role of eggshell synthesis domain containing proteins as well as the tyrosinases in egg production has been demonstrated previously (Fitzpatrick et al., 2007). On the other hand, the role of the membrane receptors CD63 antigen (CD63a) and CD63 receptor (CD63R) is not clear and will be the focus of the rest of the chapter. CD63a, but not CD63R, has previously been shown to have a pairing-dependent pattern of expression (Cogswell et al., 2012). As revealed by the time course data, both genes are not only female-specific but also respond to pairing in their expression profiles (Cluster 7 in Figure 3.10).

According to GeneDB (Logan-Klumpler et al., 2012), CD63a is a predicted 24.1 kDa protein with 225 amino acids and CD63R is a predicted 30.6 kDa protein of 276 amino acids. However, tetraspanins often undergo post-translational modifications (Termini \& Gillette, 2017), so their actual mass may be substantially higher. Tetraspanins are a group of proteins defined by their four transmembrane regions, which anchor the proteins in the cell membrane (Termini \& Gillette, 2017). They generally protrude around 3-5 nm from the cell membrane (Grove, 2014) with two extracellular regions and three short intracellular loops (Termini \& Gillette, 2017). Their roles in cell biology involve association with other proteins, including other tetraspanins, and thereby enabling the formation of signalling complexes (Levy \& Shoham, 2005).

Next I used qRT-PCR to measure the difference in gene expression between males and females at different d.p.i. for CD63a and CD63R. This was done to confirm the findings of the RNA-Seq analysis. Then, to further investigate the role of CD63a and CD63R in female fertility, in situ hybridisations and RNAi
knockdown experiments were performed to determine in which tissues these genes are expressed and whether an effect of these tetraspanins on fertility could be demonstrated.

### 3.2.9 qRT-PCR analysis of CD63 antigen \& CD63 receptor

Pairing-dependent expression of CD63R and CD63a in female worms was confirmed by qRT-PCR (Figure 3.11). Expression in female worms was measured relative to expression in male worms at 21 d.p.i. using PSMD4 (a proteasome 26 S subunit) as a reference gene (Liu et al., 2012). CD63R expression in females from MS infections was found to increase dramatically from 21 to 28 d.p.i. and remained high thereafter with expression being over 800 -fold higher in females than males at 40 d.p.i. (Figure 3.11).

CD63a expression also increased significantly in females from MS infections from 21 to 28 d.p.i compared to males, and continued to be expressed highly until 40 d.p.i. (Figure 3.12). At 21 d.p.i., females expressed CD63a at 1.25 -fold of the male expression, which increased to 56.6 -fold at 40 d.p.i., a 45 -fold increase in female expression (Figure 3.12).

Figure 3.11: Expression of CD63R significantly higher in female worms from 28 d.p.i. onwards. Expression is give as a fold change relative to male expression at 21 d.p.i. PSMD4 was used as internal reference gene for this qRTPCR analysis. Error bars are the standard error of the mean.

Figure 3.12: Expression of CD63a is higher in female than in male worms. Expression is given as a fold change relative to male expression at 21 d.p.i. PSMD4 was used as internal reference gene for this qRT-PCR analysis. Error bars are the standard error of the mean.

Both RNA-Seq and qPCR data show that there is a strong up-regulation of CD63R and CD63a expression in paired females, whereas expression in males (and, in the case of RNA-Seq data, females from SS infections) remains relatively constant at a low level (Figures 3.11 and 3.12; see Cluster 7 in Figure 3.10).

### 3.2.10 Whole mount in situ hybridisation

The cluster analysis of RNA-Seq data suggested that CD63a and CD63R could be expressed in the vitellaria of MS females and play a role in egg production. In situ hybridisation was used to identify the tissues in which expression of the two genes occurs. Tetraspanin-2 (TSP-2) was used as a positive control. TSP-2 is an abundant tegumental protein (Castro-Borges et al., 2011) and its expression at the mRNA level can be demonstrated in the cell bodies of the tegument (see Figure 3.13). These cell bodies lie outside the light brown vitelline lobes but no staining was observed inside the vitelline tissue (see Figure 3.14 for a higher magnification).

Figure 3.13: Tetraspanin- 2 is expressed in the cell bodies of the worm tegument. Alkaline phosphatase staining (Chapter 2.27) of digoxigenin-labelled tetraspanin- 2 mRNA in female worms. Expression was not observed in the vitelline tissue. F - Sexually mature female; V - Vitellarium; T - Tegument; CB Cell body. A) Whole mature female with staining located in the cell bodies of the tegument. The red rectangle indicate where the close-up in B) is derived from. B) Close-up of the female specimen in A). Stained cell bodies can be seen in the tegument. C) Close-up of a different female specimen. Stained cell bodies can be seen in the tegument demonstrating tetraspanin-2 expression there.

Figure 3.14: A close-up of the stained cell bodies indicates tetraspanin-2 is expressed in the cell bodies of the tegument. The original image is on the left; on the right the border of the vitellarium has been marked in red. V - vitellarium; T - tegument; CB - cell body.

In contrast to TSP-2, CD63a expression was detected inside the vitelline tissue of the 12 female specimens (see Figure 3.15). No expression was detected in the negative control (sense RNA) or in male worms (pictures not shown here).

Figure 3.15: CD63 antigen is expressed in the vitelline tissue of female worms. Alkaline phosphatase staining (Chapter 2.27) of digoxigenin-labelled CD63 antigen mRNA in female worms. F - Sexually mature female; V Vitellarium; T - Tegument. A) Whole female stained for CD63 antigen. B) Closeup female mid-section. C) No signal was found in the negative control.

The pattern of staining observed for the CD63R (see Figure 3.16) was similar to CD63a, showing expression in the vitellaria. Particularly, 14 female specimens displayed CD63R expression in the outer regions of the vitellaria, but little or no staining in the centre of the organ (Figure 3.15). No expression was observed in the female negative control or male worms (Figure 3.15). Erasmus (1975) described the organisation of vitellocytes. The author suggested that there is a gradient of maturity from the least mature (S1) cells at the periphery of the lobes, then S2 and S3 to the most mature (S4) cells in the centre of the female near the vitelline duct.

Figure 3.16: CD63 receptor is expressed in the vitelline tissue of female worms. Alkaline phosphatase staining (Chapter 2.27) of digoxigenin-labelled CD63 receptor mRNA in female worms. Staining was found to be most intense in the outer portions of the vitellaria. F - Sexually mature female; V - Vitellarium; T - Tegument. A) Whole female stained for CD63 receptor. A red rectangle indicate the section of the image that the close-up in B) was derived from. B) Close-up of female mid-section.. C) No signal was found in the negative control.

The results of the whole mount in situ hybridisation confirm expression in the vitellaria of mature female worms, as suggested by the cluster analysis of RNAseq data of CD63a (Smp_173150) and CD63R (Smp_155310) (Appendix A.24). However, CD63R expression seemed to take place in the outer regions of the vitellaria (Figure 3.16), possibly due to expression in particular subpopulations of vitelline cells.

### 3.2.11 RNA interference

In order to determine if CD63a and CD63R play a significant role in the production of eggs, RNA interference (RNAi) was used (Chapter 2.2.2). Soaking in dsRNA was chosen, rather than electroporation, to maintain fertility as much
as possible and the number laid eggs was the measured phenotype. The positive control knockdown, TSP-2, was successful, with qRT-PCR showing a reduction of mRNA levels to $0.5 \%$ of those in the negative control (see Figure 3.17).

In contrast, CD63R expression was found to be higher in the treated sample compared to the negative control (see Figure 3.18).

RNAi knockdown
Tetraspanin-2

Figure 3.17: Tetraspanin-2 expression was reduced significantly to $0.5 \%$ of expression in negative control. Using the 'soaking method', an RNAi knockdown of tetraspanin-2 was performed in mature females. Knocked down tetraspanin-2 expression was measured relative to the negative control samples (soaked in non-specific dsRNA) using qRT-PCR. Two biological replicates were used for treatment and the control group. "Proteasome 26S Subunit, Non-ATPase 4 " (PSMD4) was used as internal reference gene. The difference was found to be statistically significant ( $p=0.0083$ ). Error bars represent the standard error of the mean.

RNAi knockdown CD63 receptor

Figure 3.18: An increase in CD63R expression was observed relative to the negative control. RNAi knockdown in mature female worms, soaked in CD63aspecific dsRNA, was measured relative to negative negative control worms (soaked in non-specific dsRNA) using qRT-PCR. Two biological replicates were used for both treatment and control. "Proteasome 26S Subunit, Non-ATPase 4" (PSMD4) was used as internal reference gene. The difference was found to be statistically non-significant ( $p=0.086$ ). Error bars represent the standard error of the mean.

For CD63a, a moderate knockdown of around $35 \%$ was measured (see Figure 3.19). In negative controls, which did not undergo reverse transcription, amplification was only observed over six cycles after amplification in the samples suggesting that the DNase treatment successfully removed most potential gDNA contamination (Appendix A.25). In the no template control, amplifcations was only observed over 10 cycles after amplification in the sample showing that little non-specific amplification was taking place (Appendix A.25). TSP-2 is expressed in the tegumental cell bodies (Tran et al., 2010), which may be more accessible to the dsRNA than the vitellarian tissue deeper inside the worm. This may explain why the TSP-2 knockdown was successful compared to the CD63a and CD63R knockdowns.

RNAi knockdown
CD63 antigen

Figure 3.19: A moderate knock of CD63a expression of 35\% was observed. RNAi knockdown of CD63R was measured in mature females relative to the negative control (worms soaked in non-specific dsRNA) using qRT-PCR. Two biological replicates were used for both treatment and control. "Proteasome 26S Subunit, Non-ATPase 4" (PSMD4) was used as internal reference gene. The difference was found to be just short of statistical significance ( $p=0.053$ ). Error bars represent the standard error of the mean.

Figure 3.20: Reduction in laid eggs by the CD63a \& CD63R knock-down worms was not statistically significant. An ANOVA showed that the treatment groups did not differ sginificatnly from the negative control ( $p=$ 0.485). Egg production was measured as a phenotype of RNAi knockdown. Eggs were counted two days after RNAi knockdown began. The number of eggs is given per female. Error bars represent the standard error of the mean of the three biological replicates.

A moderate reduction in eggs was observed in both knockdown groups relative to the negative control group (see Figure 3.20), although no strong reduction in gene expression could be demonstrated and in the case of CD63R a $50 \%$ higher expression was measured compared to the negative control. However, because only two biological replicates could be set up for each condition, an analysis of variance (ANOVA) found there to be no statistically significant difference between the groups ( $\mathrm{p}=0.485$ ).

In the RNA-seq data, high levels of CD63R expression were observed in mature females. However, the qRT-PCR analysis indicated low expression of CD63R in the control and the treated samples. Therefore, I investigated whether there was a change in mRNA expression between freshly perfused worms and those
cultured in vitro for seven days, as had been done for the knockdown experiment. From the batch of worms used for the RNAi soaking experiment several worms had been placed in Trizol directly following the perfusion, which were used as in vivo control.

The qRT-PCR analysis showed that CD63R expression was 230 -fold higher in freshly perfused worms compared to worms after seven days in vitro, whereas CD63a expression was only 14 -fold higher in the freshly perfused worms compared to worms after in vitro culture (see Figure 3.21), probably due to the fact that CD63a is expressed at higher base levels in all worms compared to CD63R. Some down-regulation of these genes in vitro had been anticipated even in the negative control because of the regression of female fertility in cultre (Galanti et al., 2012). However, the extent to which expression of CD63a and CD63R declined was unexpected. The down-regulation in mRNA expression with such a large effect size both in the control and RNAi treated worms is likely to interfere with an accurate measurement of the effect of the RNAi treatment and obscure the effect of the RNAi knock down.

Figure 3.21: Expression of CD63 receptor (left) and CD63 antigen (right) was significantly higher prior to in vitro culture. Expression was measured in freshly perfused (ex vivo) worms and worms cultured for seven days (in vitro). For both qRT-PCR reactions PSMD4 was used as internal reference gene. The differences in expression were statistically significant for both genes (CD63R: p = 0.016 ; CD63a: $p=0.036$ ). Error bars represent the standard error of the mean.

The experiment showed that TSP-2 mRNA levels could be depleted by approximately $99.5 \%$ by soaking worms in dsRNA (Figure 3.17). However, the soaking did not reduce CD63R mRNA and only resulted in a mild reduction of CD63a mRNA. To facilitate better access of dsRNA molecules to the deeper tissues such as the vitellarium, the treatment was repeated, using electroporation instead of simple soaking as well as a shortening of the experiment from one week to 48 hours. A potential disadvantage of electroporation is the greater level of stress caused to the female and the impact on their egg production this might have, which could obscure any subtle effect the knockdown might have on egg production. The length of the experiment was also shortened to lessen the effect of in vitro culturing and reduce the decline in CD63a and CD63R expression in the negative control that was demonstrated previously.

In this RNAi experiment, a very moderate reduction of about $16 \%$ in CD63R mRNA levels was observed (Figure 3.22). This reduction was well within the standard error of the normalised expression levels (see Figure 3.22). The results of this experiment did not allow the null hypothesis to be rejected. With more replicates it might be possible to determine, whether the small observed effect seen was reproducible or due to chance. Nonetheless, this result is an improvement on the previous soaking knockdown where an increase in CD63R mRNA levels was observed in the treated sample relative to the negative control.

Figure 3.22: No significant knock-down of CD63 receptor expression was observed. RNAi knockdown of CD63 receptor using the 'electroporation method' was measured relative to the negative control sample (electroporated with non-specific dsRNA) using qRT-PCR. PSMD4 was used as internal reference gene. The difference in expression was not found to be statistical significant ( $\mathrm{p}=$ 0.822 ). Error bars represent the standard error of the mean.

In the CD63a knockdown experiment, a statistically significant $(p=0.044) 47 \%$ reduction in CD63a mRNA levels was measured with much smaller standard errors measured compared to the CD63R knockdown (see Figure 3.23). In this experiment, the knockdown was found to be more successful than the soaking
experiment [reduction by $\sim 35 \%$ (Figure 3.19)]. Taken together, these results suggest that CD63a is targetable by RNAi.

For measuring expression of both CD63R and CD63a, PSMD4 was used as a reference gene. The negatve controls, that had not been reverse transcribed, only showed amplification about seven cycles after the samples suggesting that the DNase treatment successfully removed most gDNA contamination (Appendix A.26). The no-template controls showed no amplification until about ten cycles after the samples suggesting that there was little non-specific amplification (Appendix A.26).

RNAi knockdown CD63 antigen

Figure 3.23: A significant knock-down in CD63 antigen expression was observed. RNAi knockdown of CD63 antigen using the 'electroporation methods' was measured relative to the negative control sample (electroporated with nonspecific dsRNA) using qRT-PCR. PSMD4 was used as internal reference gene. The difference in gene expression was statistical significant (p = 0.044). Error bars represent the standard error of the mean.

Figure 3.24: The number of laid eggs was reduced significantly in the CD63a and CD63R knockdown worms. The number of eggs per female is plotted for the knockdown of CD63 antigen, the negative control and the CD63 receptor; three replicates were available for each condition. The eggs were laid during the 48 hours following RNAi electroporation. An ANOVA showed that the treatment groups laid significantly fewer eggs compared to the negative control ( $\mathrm{p}=0.0156$ ). The analysis also showed that both, the CD63a and CD63R knockdown resulted in a significant reduction of eggs compared to the negative control (CD63a: $p=0.00679$; CD63R: $p=0.0201$ ).

Again, a reduction in egg laying was observed in both knockdown experiments (see Figure 3.24). A 9.6-fold reduction of egg laying was observed in worms with knocked down CD63a expression and a 3.2 -fold reduction in worms with knocked down CD63R expression, relative to the negative control (Figure 3.24). Here, three biological replicates were analysed and the observed reduction in eggs laid was greater than in the soaking experiment (Figure 3.20). As a result, an ANOVA showed that the reduction in eggs laid was found to be statistically significant ( $\mathrm{p}=0.0156$ ) but also that CD63a and CD63R knockdowns significantly affected egg production compared to the negative control (CD63a: $p$ $=0.00679$; CD63R: $p=0.0201$ ). Notably, the number of eggs was overall much lower (approximately 10\%) compared to the egg counts in the soaking
knockdown experiment (compare Figures 3.20 and 3.24), which might be due to the effect of electroporation on the females. Although only a moderate reduction of mRNA was observed for CD63a, the significant reduction in egg production is strongly suggestive of a real effect and not chance. This is especially true, as CD63a expression was reduced to a similar extend in the soaking experiment where egg laying was also reduced (albeit not statistically significant) and therefore showing the same trend (compare Figures 3.20 and 3.24).

CD63R expression, however, was reduced to a much smaller extent (Figure 3.23), yet a phenotype was measured at the egg laying level (Figure 3.24). This was also observed in the soaking experiment, where a (non-significant) reduction in egg production was observed (Figure 3.20). At worst, this could suggest that the egg laying phenotype is not a suitable phenotype, as egg production can be sensitive to many other factors, such as stress and injury caused during the perfusion. If this is the case, then a lot of random fluctuations should be seen within replicates. To some extent this can be seen, certainly in the negative control, but also CD63R (Figure 3.24). However, the egg counts for the CD63a were remarkably similar (5, 5 and 3 eggs in each well respectively) and much smaller than even the lowest negative control sample (Figure 3.24). A similar trend was observed in the soaking experiment, giving me further confidence that the observed effect of the CD63a knockdown on egg production was real.

### 3.3 Discussion

The aim of this chapter was to perform an analysis of gene expression of the developing male and female worms inside the mammalian host. The differential expression analysis reproduced many findings in the published literature, validating the approach. The analysis of male worms showed clearly that the male transcriptome was largely unaffected by pairing, with only a handful of genes consistently differentially expressed between males from SS and MS infections (Leutner et al., 2013). Females on the other hand are known to mature in a pairing dependent manner from the fourth week of infection (Biolchini et al., 2006), with my RNA-Seq data showing the greatest increase in differentially expressed genes between females from SS and MS infections between 21 and 28 d.p.i. Also, in MS infections, egg laying was observed from 35 d.p.i. onwards in addition to egg production related gene expression reaching its peak at 35 and 38 d.p.i. This includes genes encoding eggshell synthesis domain containing proteins, tyrosinases, extracellular superoxide dismutases, as well as genes coding for the tetraspanin CD63 antigen and receptor, showing that paired female worms reached sexual maturity around this time. Another up-regulated gens was TRAP1, a heat shock protein mainly localised to the mitochondria, that protects cells from oxidative stress by inhibiting the respiratory complex II and protecting the cell from apoptotosis (Guzzo et al., 2014). Tyrosinases expressed in the vitellaria are essential for proper egg development in schistosomes (Fitzpatrick et al., 2007). However, tyrosinase activity is generally thought to result in oxidative stress, as it has been shown in other systems such as mosquitoes (Christensen et al., 2005). The extracellular superoxide dismutase
and TRAP1 may help cells in the vitellaria to cope with the oxidative stress resulting from the tyrosinase activity to prevent damage to the tissue and allow a high rate of continuous egg production. Together, the results confirmed many findings of the published literature (Fitzpatrick \& Hoffmann, 2006; Leutner et al., 2013) but provided a more comprehensive picture of when these sex specific genes become differentially expressed.

When comparing male and female worms at different time points, but particularly at 38 d.p.i., a significant up-regulation of nicotinic receptors was observed in male worms (Table 3.3). Nicotinic receptors represent a group of drug targets in many parasitic nematodes which are targeted by anthelmintics such as levamisole, pyrantel and oxantel (Williamson et al., 2009). These drugs cause the ligand-gated ion channels to open, resulting in "prolonged muscle contraction and spastic paralysis of the worms" (Williamson et al., 2009). Such receptors have recently also become of interest as a drug targets for S. mansoni as described by MacDonald et al. (2014). The authors observed that the $S$. mansoni nicotinic acetylcholine receptors do not exert an excitatory effect on the neuromuscular system as in mammals and nematodes, but instead function as inhibitory neuromuscular receptors (MacDonald et al., 2014). MacDonald et al. (2014) localised two of these proteins to the worm surface as well as in nerves. Therefore, the up-regulation of neurotransmitter receptor genes in male worms could be the result of the greater surface area as well as greater proportion of muscle tissue in male worms in comparison to mature female worms.

During the analysis of the juvenile male worm, genes related to the cytochrome P450 related drug metabolism were found to be up-regulated. Cytochrome P450dependent metabolism plays an important role in processing praziquantel in humans (Li et al., 2003) but whether this is true for schistosomes is not clear. This pathway was found to contain several differentially expressed genes encoding glutathione S transferases, one of which (Smp_102070) has previously been shown to bind praziquantel and play an important role in the detoxification of S. mansoni (McTigue et al., 1995; Cardoso et al., 2003). Another GST encoding gene (Smp_024010) was also found to be down-regulated after 18 d.p.i.. From day 18 to 38 , its expression decreased 21.9 and 18.2 -fold in male and female worms respectively, potentially making the worm more susceptible to the effects of praziquentel. McTigue et al. (1995) showed that homodimers of GST bind praziquantel at the dimer interface, not in their substrate-binding site and concluded that praziquantel inhibits GST activity, which leads to a build-up of reactive oxygen species and toxic metabolites inside the parasite, in particular cytotoxic free radicals. Cardoso et al. (2003), on the other hand, concluded that the binding of praziquantel to GST had a protective effect on the worm by keeping praziquantel away from its real cellular target [for example voltage operated calcium ion channel (Nogi et al., 2009)]. Given the rapid effect of praziquantel on schistosomes (Xiao et al., 1985), a build-up of reactive oxygen species and toxic metabolites does not seems as plausible as the conclusion of Cardoso et al. (2003). However, in either case, a greater expression of GST encoding genes such as Smp_102070 and Smp_024010 would confer a protective effect on the schistosomes.

When examining the expression of testes related genes, a number of interesting similarities and differences were observed between males from SS and MS infections. The comparison between male worms from MS infections at 21 and 28 d.p.i. revealed that they appear to use a similar mechanism to prevent the premature proliferation of prospermatogonia as mammals. Basonuclin 2 (Smp_138350), a testes specific gene in mammals and S. mansoni, was found to be up-regulated in male worms from SS and MS infections prior to pairing at around 28 d.p.i. Vanhoutteghem et al. (2014) reported that "basonuclin 2 is required for proper mitotic arrest, prevention of premature meiotic initiation and meiotic progression" of germ cells. In knock out mice, prospermatogonia multiply excessively leading to accumulation of spermatocytes and ultimately apoptosis during meiotic prophase (Vanhoutteghem et al., 2014). Adult male worms are known to produce sperm in the absence of a female partner (Armstrong, 1965); therefore, the role of this gene in schistosomes may be to allow male worms to mature sufficiently before investing energy into sperm production. However, differential regulation of genes potentially involved in sperm production were also observed. Neves et al. (2005) demonstrated morphological differences between the testes of males from SS and MS infections, despite both producing sperm. In the male time series analysis, genes encoding the FGF receptor activating protein (Smp_035730, adjusted p-value $=$ 0.0053 ) and the epidermal growth factor receptor (Smp_152680, adjusted pvalue $=0.0069$ ) were found to be up-regulated in paired males. These genes were shown to be expressed in the testes at significantly higher levels than in other organs (see Chapter 5). Both FGF and the EGF signalling pathways regulate cell proliferation and differentiation (Eswarakumar et al., 2005; Herbst, 2004).

This may assist to regulate sperm production in male worms and allow unpaired male worms to conserve energy.

In female worms from $S S$ and $M S$ infections, a much larger number of differentially expressed genes were observed than in male worms. When examining females between 21 and 28 d.p.i. a large proportion of the significantly regulated genes were found to encode transcription factors. This included approximately a third of the genes up-regulated at day 21 (37/119), suggesting that some developmental processes finished then, but also that the regulation of the transcriptome is changing significantly around the time pairing is thought to occur. Interestingly, a comparison of females from SS and MS infections at 28 d.p.i. showed that down-regulation of these genes encoding transcription factors occurs independently of pairing at this stage of the worm development. Female worms became developmentally arrested around this time in the absence of male worms (Figure 3.2), which stimulate further maturation. The down-regulation of these genes coding for transcription factors probably marks the beginning of this developmental arrest. However, at least six genes encoding transcription factors were found to be up-regulated at 28 d.p.i., four of which were found to be consistently associated with sexual maturity in female worms, with expression being pairing-dependent. Expression of these four genes was detected at very low levels in most samples, but a significant increase in expression in females from MS infections was measured from 28 d.p.i. onwards. Although their precise function remains unknown, their expression patterns over the RNA-Seq time course caused them to be clustered with genes expressed
predominantly in the vitellaria of mature female worms. This is further evidence of a changing regulation of transcription in paired females.

Using two clustering algorithms, MBCluster and Kohonen, a set of 76 female specific genes putatively involved in egg production was identified, a subset of which has previously been shown to play important roles in female reproduction (for example Fitzpatrick et al., 2007; Fitzpatrick \& Hoffmann, 2006). Due to their functions as cell surface receptors and their potential involvement in signalling, the CD63 antigen and tetraspanin CD63 receptor stood out. Further investigation with qRT-PCR confirmed the RNA-Seq expression patterns. Both genes were expressed in paired females, beginning around 28 d.p.i. To get more insight into the role of these genes and add evidence for their role in egg production whole mount situ hybridisation (WISH) and RNAi knockdown experiments were performed for both genes. The WISH experiments showed that both genes were expressed in the vitellarian tissue of the female worms, although the CD63 receptor was expressed in the outer portions of the vitellarium, whereas the CD63 antigen was found to be expressed throughtout the vitellarian tissue.

The RNAi knockdown experiment proved challenging. In the first round of knockdowns, using a soaking technique, the positive control, TSP-2, worked well with a reduction of mRNA to $0.5 \%$ of the original expression. However, knockdown efficiency for CD63a and CD63R was far less satisfactory. CD63a expression had been reduced by $35 \%$ whereas expression of CD63R was measured to be 53\% higher after RNAi treatment compared to the control samples. This unexpected result may have been caused by the effects of the in
vitro culture. Worms were found to have significantly lower expression of CD63a ( $\sim 14 \mathrm{x}$ ) and CD63R ( $\sim 230 \mathrm{x}$ ) after in vitro cultre, compared to freshly perfused worms (Figure 3.21). It has previously been shown (Galanti et al., 2012) that female worms lose maturity and regress outside their host even in the presence of male worms; however, the extent of this effect was greater than expected. In a repeat of this experiment, I opted to reduce the length of the in vitro culture after RNAi treatment to 48 h , instead of 7 days. Furthermore I chose to use electroporation rather than soaking in the second experiment to maximise probe penetration, at the expense of worm fitness. This experiment proved to be more successful with a measured reduction of CD63R mRNA of $16 \%$ (instead of a measured increase) and a reduction of CD63a mRNA of 47\% (instead of 35\%). Finally, the number of eggs laid by the RNAi treated worms was significantly reduced for both CD63R and CD63a by 3.2 and 9.6 -fold respectively, suggesting that both genes play a role in the production of eggs. The CD63 antigen is known in humans to form complexes with integrins and act as part of signalling complexes that regulate cell proliferation and differentiation (Tugues et al., 2013). For example CD63a is known to interact with syntenin-1 - an adaptor protein regulating vesicle formation and TGF- $\beta$ mediated SMAD activation (Hwangbo et al., 2016) - and other adaptor proteins of the clathrin-dependent endocytosis pathway (Charrin et al., 2014) as well as the "tissue inhibitor of metalloproteinase-1" and integrins (Jung et al., 2006). The interactions with syntenin-1 and the adaptor proteins occur at the same location on the CD63a protein and are thought to be mutually exclusive (Berditchevski \& Odintsova, 2007). By interacting with syntenin-1, CD63a might play a role in the regulation of TGF- $\beta$ signalling as well as the formation of vesicles, potentially in the
vitellocytes of the maturing female. Mature (S4) vitellocytes are known to contain a large number of vesicles containing eggshell protein precursors (Cogswell et al., 2012). The CD63 receptor, on the other hand, may play a role in endocytosis via clathrin-dependant as well as independent pathways (Berditchevski \& Odintsova, 2007) and may aid in the formation of the vitelline cells' secretory vesicles that will later go on to form the eggshells. Another mechanism by which CD63 antigen may regulate vitelline proliferation, namely apoptosis, will be examined in more detail in Chapter 5.

Chapter 4

Transcriptome analysis of sexually regressing S. mansoni

### 4.1 Introduction

The sexual maturity of female schistosomes is pairing-dependent, a trait of their biology that requires close contact to a male partner for the ovaries and vitelline tissue of the female to develop fully. Female reproductive tissues regress when the male partner is no longer present, and regenerate upon re-pairing.

Galanti et al. (2012) performed a series of experiments in order to examine the contribution of pairing on apoptosis and cell proliferation and the resulting effect on the growth and shrinkage of the female reproductive system. They involved culturing mature female worms ex vivo for up to 11 days either paired with a male or in the absence of a mate and recording their size and egg laying. They also measured the gene expression of an eggshell protein, p14, the rate of mitosis and apoptosis in female worms, which served as a marker of female sexual development. The results showed that both paired and single females regress sexually in ex vivo culture but, importantly, that paired females undergo this regression more slowly, retaining cellularity in their vitelline tissue and expressing p14 at higher levels, albeit lower than in vivo. Based on the relative amount of TUNEL (for apoptotic cells) and BrdU (for dividing cells) staining observed in paired and separated females, Galanti et al. (2012) also concluded that growth and shrinkage of the vitelline tissue is primarily regulated by the rate of apoptosis, not proliferation, and that unpaired females have more apoptotic cells. These results highlighted two things in particular: a pairingspecific effect on the females that can even be observed during ex vivo culture and secondly that in the culture conditions used by Galanti et al. (2012), females
do not retain their mature state independent of the pairing status. In their discussion, reference is made to a richer media (Basch, 1988) that better supports female fertility, although still not perfectly.

Work described in this chapter examined the changes in gene expression that take place in unpaired females compared to those that remain paired over time. By examining the mechanism by which female $S$. mansoni undergo regression of their reproductive tissues at the transcriptome level, new avenues for preventing or treating schistosomiasis may be uncovered.

Following a series of testes with different culture conditions Basch medium was chosen for this experiment to minimise the loss of fertility of females due to $e x$ vivo culture. The length of the experiment was set to 8 days, based on qPCR results (Galanti et al., 2012). These showed that single females expressed significantly lower levels of p14 than paired females from day 7 and that expression levels do not fall much further from then until day 11 . Worms were perfused from mice and sorted by sex. Some males and females were immediately placed in separate microcentrifuge tubes containing Trizol (day 0) for RNA extractions. The remaining worms were split into three groups and maintained ex vivo using modified Basch medium (see methods). The three groups consisted of single male, single female and paired worms. After 4 and 8 days, half of each group was placed in Trizol (paired worms were separated beforehand), RNA was extracted from all samples and RNA-Seq libraries were prepared as before (see methods).

Based on the results described in Chapter 3, I expected to find a reduction of the expression of fertility related genes in single females when compared to paired females but also in paired females when compared to day 0 females. Examples of such fertility related genes include eggshell protein (Smp_000430), various eggshell synthesis domain containing proteins, major egg antigens and female specific genes (Smp_077900 \& Smp_000290). Furthermore, based on the results by Galanti et al. (2012), I also expected to find evidence for increased levels of apoptosis in females cultured in vitro for 8 days - especially in single females - at the transcriptome level.

Previous publications have gathered a list of apoptosis related genes of Schistosoma. Peng et al. (2010) discovered and characterised an inhibitor of apoptosis (SjIAP) in S. japonicum, which they propose belongs to a conserved group of negative regulators of apoptosis with homologues in H. sapiens, C. elegans and D. melanogaster. Using both S. japonicum cell lysate and transformed human 293T cells, inhibition of apoptosis by SjIAP was demonstrated. Using the sequences of human genes regulating apoptosis, namely the Bcl-2 family, Lee et al. (2011) identified eight Bcl-2 related genes in S. mansoni with a variety of domain architectures. More recently Lee et al. (2014) published a summary of eleven apoptosis regulating genes, including five members of the Bcl-2 family: Bcl-2, Bak, Bcl-2 2, BH1 and BH3. They also identified an Apaf1 homologue, four caspase homologues and included the $S$. mansoni ortholog of the SjIAP gene characterised by Peng et al. (2010), which they noted shares no relation to other IAP proteins.

Figure 4.1: Apoptosis in S. mansoni. Black arrow - activation; red arrow inhibition; dashed arrow - indirect interaction. The S. mansoni apoptosis pathway is similar to that of mammals, including a Fas receptor homologue and associated proteins, a caspase cascade, involvement of the mitochondria via Bak/Bax and Bcl-2 homologues as well as a cell cycle dependent apoptosis regulators such as PAK. Diagram modified from Lee et al. (2014) and the Kyoto Encyclopedia of Genes and Genomes (KEGG) website (2012). Abbreviations: FasR, Fas Receptor; FAF, Fas Associated Factor; FBF, Fas Binding Factor; FADD, Fas Associated Death Domain; Casp, Caspase; IAP, Inhibitor of Apoptosis Protein; APAF1, Apoptotic Protease Activating Factor; CytC, Cytochrome C; Bak, Bcl-2 homologue antagonist/killer; Bcl, B Cell Lymphoma; BH3, Blc-2 homology 3; PAK1, p21 activated kinase 1; PAK1IP, PAK1 Interacting Protein; PPP1R13B, Apoptosis-Stimulating of p53 Protein1.

Despite these efforts, there are still considerable gaps in our understanding of the putative schistosome apoptosis pathway as summarised in Figure 4.1. The presence of Bak and Bax homologues in S. mansoni suggests involvement of the mitochondria in schistosome apoptosis as their function in other higher eukaryotes is to puncture the mitochondrial outer membrane and form pores in it (Westphal et al., 2011). Furthermore, the Bcl-2 and BH3 homologues may be involved in the regulation of Bak/Bax activity, which leads to permeabilisation of the mitochondrial outer membrane and the release of cytochrome C and activation of the caspase cascade (Westphal et al., 2011). In S. mansoni four caspase homologues have been identified which could be activated by cytochrome C via the apoptotic protease activating factor 1 (APAF1). Induction of apoptosis can occur either from within the cell, by proteins regulating the cell cycle and detecting critical DNA damage or by extracellular signals that stimulate the Fas receptor family. There are several apoptosis regulating genes that link the $S$. mansoni cell cycle to its apoptotic machinery including homologues of the p21 activating kinase (PAK) and an PAK interacting protein 1 (PAKIP1) as well as a p53 apoptosis stimulating factor (PPP1R13B). There is also a pro-apoptotic "death receptor", a homologue of FAS, as well as four homologues of FAS receptor interacting proteins including a FAS-Associated protein with Death Domain (FADD) homologue, a key mediator of pro-apoptotic signalling, which links the Fas receptor to caspase activation in mammals.

The ability of sexually mature female worms to regress to a more juvenile stage when unpaired is an intriguing aspect of schistosome biology. The work in this chapter aimed to examine how the expression of apoptosis-related genes
changes during the regression of female reproductive tissue. To do so, female worms were kept either by themselves or with a male worm in vitro for up to eight days. Several technical issues were encountered during the data analysis for this chapter, so that the focus of the chapter shifted to also examine the effect of in vitro culture on gene expression in male and female worms.

### 4.2 Results

### 4.2.1 Optimising culture media

In order to maintain worms in vitro, different culturing conditions were tested, particularly, different media and red blood cell concentrations. The number of eggs laid by female worms over the course of 28 days was used as a measure for the healthiness of cultured worms. The tests with different culturing conditions showed that Basch medium resulted in an approximately 6 -fold more eggs being laid (see Figure 4.2) compared to a less complex, RPMI-based medium (see Chapter 2.1.5). While female worms in Basch medium were found to have laid approximately 190 eggs on average, females in the RPMI based media only laid around 30 eggs. Using a $t$-test the average number of eggs for both samples was significantly different ( $p<2.2 \mathrm{E}-16$ ).

Figure 4.2: Significantly more eggs were laid in Basch media compared to RPMI. Box plot of eggs laid per female in RPMI based medium and Basch medium after 28 days in in vitro culture. Both groups contained 36 paired females. Using a Welch two sample $t$-test, a significant difference between the numbers of eggs laid by both groups was found; $p<2.2 \mathrm{E}-16$.
Furthermore the addition of red blood cells (RBC) was shown to increase the rate of egg laying. 1\% RBC resulted in the highest number of eggs being laid (an average of 178 eggs), $0.1 \%$ resulted in fewer eggs (an average of 122 eggs) and no RBC resulted in the lowest number of eggs being laid (an average of 86 eggs) (see Figure 4.3). These differences were found to be statistically significant using a $t$-test; for $0.0 \%$ and $0.1 \%$ RBC $p=0.010$; for $0.1 \%$ and $1.0 \% p=3.3 \mathrm{E}-04$.

Figure 4.3: Significantly more eggs were laid in media enriched with $\mathbf{1 . 0 \%}$ red blood cells compared to $\mathbf{0 . 0 \%}$ and $\mathbf{0 . 1 \%}$. Box plot of eggs laid per female in Basch medium with varying amounts of red blood cells (by volume) after 28 days in in vitro culture. All groups contained 24 paired females. Using a Welch two sample $t$-test, significant differences between the numbers of eggs laid by the three groups were found.

For the main experiment, testing the effect of unpairing on the female transcriptome, the culture conditions with the best egg laying results were chosen: Basch medium with a $1 \%$ concentration of RBC. In total 100 worms, 50 female and 50 male, were used in this experiment. RNA-Seq libraries in this experiment were obtained from single worms. 10 biological replicates were set up for each time point and pairing condition, however due to the small quantities of RNA isolated from single worms only 60 out of the 100 libraries were completed successfully. While for some samples the RNA extraction failed entirely, other samples contained degraded RNA. Overall at least four biological replicates were successfully produced for each samples group. At the beginning of the experiment (day 0 ) the selected females were all sexually mature and paired. Both groups, paired and unpaired, remained visibly unchanged by day 8 ,
except that in both groups the stomachs of female worms appeared less darkly coloured. This suggests that despite the addition of RBC to the Basch medium the rate of feeding was lower during in vitro culture.

### 4.2.2 Apoptosis related genes

In preparation for the functional interpretation of the differential expression analysis, apoptosis related genes were identified. In order to determine whether any significant up-regulation of apoptosis occurred in the unpaired females when compared to the females that remained paired throughout the 8 days, I first compiled a list of apoptosis related genes both from the literature (Lee et al., 2011, 2014; Peng et al., 2010) as well as by using BLAST to identify other homologues of known apoptosis genes in the S. mansoni genome (see Chapter 2.4.12). In total, 29 genes were found but two were subsequently removed (see Appendix B.2-10 for details on the function and domains of the apoptosis related genes). These two genes, Smp_041630 and Smp_043360, had been initially identified from the literature, but had neither relevant Pfam domains nor significant BLAST hits to known apopotosis related genes (Table 4.1) and were excluded from the analysis. This was most likely the result of changes to the gene models.

Table 4.1: Summary of Schistosoma mansoni putative apoptosis-related genes. This table provides S. mansoni gene IDs, product names and their Homo sapiens or Caenorhabditis elegans homologues with BLAST scores, e-value and coverage. The total score is the number of sequence matches between the query and the subject sequences. Query coverage is the proportion of query sequence covered by the subject sequence. The Expected (E) value is a measure of how probable the given alignment is by chance. The identity is the extent to which query and subject sequences have the same amino acids in the same position, given as percentage.

### 4.2.3 Sequencing \& sample clustering

Illumina libraries were prepared from 50ng of total RNA as outlined in Chapter 2. In total Illumina sequencing produced nearly 2.2 billion reads, with 10.7-75.8 million reads per sample (average 36.5 million) (see Appendix B.1). Of those reads, on average $90 \%$ were successfully mapped to the $S$. mansoni reference genome using TopHat2 (see Appendix B.1). The unmapped reads were mostly multimers of adapter and PCR primers, which cannot be completely removed during the size selection step of library preparation.

A principal component analysis was performed using DESeq2 It showed how well samples from each experimental group clustered together and how similar the groups were to one another (see Figure 4.4). Male and female samples clustered separately and the PCS suggests that the transcriptomes of paired and separated worms changed over the course of the 8 -day experiment (Fig. 4.4). However, many samples did not cluster by treatment. While male worms from different time points separated relatively well, paired and separated males at each time point did not form discrete groups (Fig 4.4). Overall, the first two principal components explained $67 \%$ of the variability of samples, most of which was attributable to differences between male and female worms (Fig 4.4).

Figure 4.4: Samples clustered well by gender, but separated less well by time in vitro and pairing status. Principal component analysis (PCA) plot of RNA-Seq samples at 0,4 and 8 days after perfusion. The RNA-seq samples separated into female (left) and male (right) clusters but samples separate poorly by treatment (paired and separated).

### 4.2.4 Comparison of pairing and separated females at day 8

The PCA plot (Figure 4.5 B) of paired and separated females at day 8 shows that the separated females (blue) showed greater transcriptome variability than paired females. However, the groups did not separate well and in fact overlapped. Compared to the paired females, the PCA plot showed that separated females responded to separation less uniformly and that the treatment introducted greater variability of gene expression at the transcriptome level.

Figure 4.5: Most differentially expressed genes were up-regulated in separated females. Pair-wise comparison of paired and unpaired females at day 8 after perfusion. A) The Log ratio against mean (MA) plot showed only one differentially expressed gene (marked with arrow) was up-regulated in paired females, all others in separated females. Blue lines indicate 2 -fold expression change. B) A principal component analysis of RNA-seq data from paired and separated females. The gene expression data of separated females grouped less tightly, but overlapped with the data of paired female samples.

Out of a total of 10,828 genes with non-zero read counts, 9464 ( $92 \%$ ) were removed from the analysis using the DESeq2 independent filtering algorithm, and 297 were removed as outliers, based on their Cook cut-offs (Chapter 2.4.4), a single gene (Fig 4.6) was found to be up-regulated in paired females but 149 were up-regulated in single females (see Appendix B. 11 for expression data of the DEGs of this chapter). Due to the high variability between biological replicates (Fig 4.5 B) the RNA-Seq analysis yielded a relatively low number of differentially expressed genes when compared to Chapters 3 and 5. Here, the default p -value threshold for the DESeq2 package (adjusted p -value $<0.1$ ) was used to determine significance. In Chapters 3 and 5, the large number of identified DEGs allowed for a more stringent selection to remove a higher
proportion of false positive results. To increase the statistical power of this analysis, DESeq2 removed a large proportion of genes from this part of the analysis based on the independent filtering algorithm, as mentioned above. Genes with a smaller average expression than 6350 reads per sample were removed from this comparison. This is done to remove genes with low absolute expression, which have little chance of being found to be differentially expressed. As a result, the p-values of the remaining genes have to be adjusted less harshly for multiple hypothesis testing.

The gene found to be up-regulated in paired females codes for the major egg antigen (p40) (Smp_049270; 3.7x change, adjusted p -value $=0.046$ ) (Table 4.2). Finding reproduction and fertility related genes up-regulated in the paired females was expected; however, many of the genes found to be up-regulated in the unpaired females were also associated with these aspects of female biology (Appendix B.11). These include genes coding for an eggshell protein (Smp_000430; 3.6x change, adjusted p-value $=0.089$ ) and a trematode eggshell synthesis domain containing protein (Smp_077890; 3.0x change, adjusted pvalue $=0.089$ ). Furthermore, genes found in Chapter 3 to be associated with pairing in vivo were found to be expressed at significantly higher levels in the single females compared with the paired females, including the genes coding for the CD63 receptor (Smp_155310; 3.8x change, adjusted p-value $=0.078$ ) and the CD63 antigen (Smp_173150; 3.1x change, adjusted p -value $=0.089$ ) which were the $9^{\text {th }}$ and $27^{\text {th }}$ most up-regulated genes in single females respectively (Appendix B.11). A striking number of mitochondrial genes (8 out 150 DEGs), but even more ribosomal genes ( 48 out 150 DEGs) was found to be differentially
expressed, suggesting that unpaired females have a higher metabolic rate and greater rate of protein synthesis, both of which seems contradictory to the published literature given that pairing is associated with growth and reproduction (Fitzpatrick \& Hoffmann, 2006; Sun et al., 2015). None of the apoptosis related genes from my gene set were found to be differentially expressed (see Appendix B.11).

Table 4.2: The 20 most differentially expressed genes identified in the comparison of paired and separated females at day 8 after perfusion.
Average read counts provide a measure of absolute expression for a given gene. The fold changes reflect expression in separated females relative to paired females. Notably only a single gene (Smp_049270) was significantly up-regulated in paired females. The $p$-value has been adjusted for multiple hypothesis testing.

Figure 4.6: Biological replicates of separated females have great variability in gene expression. This is a box whisker plots of normalised read counts, a measure for absolute gene expression, for all RNA-seq samples of paired and separated females at day 8 after perfusion. In all genes, with the exception of Smp_049270 (coding for the major egg antigen), the expression is less uniform and more variable in the separated females compared to paired females.

### 4.2.5 Comparison of pairing and separated males at day 8

The PCA plot (Figure 4.7 B) of paired and separated males at day 8 shows three relative outliers, one from the separated and two from the paired males. The remaining samples there do not separate into two groups but overlap. Given that pairing has been shown to have a very limited impact on the male transcriptome (Leutner et al., 2013), it was not surprising that separation only had a small effect on the transcriptome. Furthermore, as the MA plot (Figure 4.7 A ) shows, there were only small fold changes of gene expression between the two groups.

Figure 4.7: The low number of differentially expressed genes between separated and paired males has small fold changes. Pair-wise comparison of paired and separated males at day 8 after perfusion. A) The log ratio vs mean (MA) plot showed that none of the differentially expressed genes have a fold change greater than $2(\log 2$ fold change $>1)$, indicated by the blue lines. This small effect size stood in contrast to the female comparison where much bigger fold changes in expression were found. B) Principal component analysis of paired and separated males showed outliers in both groups but also that the two groups of males did not separate, suggesting a very limited effect of the treatment.

In the comparison of female samples, differential expression analysis identified only 150 DEGs despite there being over 900 genes with greater than two-fold change in expression (Figure 4.5), the result of high variance within biological replicates (Figure 4.6). In this comparison of male worms on the other hand, 42 DEGs were identified but not a single gene was found to have a greater than twofold change in expression (Table 4.3).

In the comparison of paired and separated male worms at day 8 , a total of 18 genes were found to be up-regulated in paired, and 24 genes up-regulated separated males (Fig. 4.7A and Table 4.3). This is out of a total of 10172 genes with non-zero read counts, of which 2029 (20\%) were removed using the independent filtering algorithm of DESeq2. The cut-off used for filtering was an mean expression of fewer than 78 reads. The cut-off used to determine differential expression was again an adjusted p-value $<0.1$, which is the DESeq2 default. Noticeably, unlike in the female comparison where the median fold change of DEGs was 2.5 x change, the fold changes for the male DEGs were smaller, ranging from $1.8 x$ change in expression to as small as $1.12 x$ change, with a median fold change of only 1.3 x for DEGs (Table 4.3). Several genes encoding proteins with structural functions were differentially expressed in separated males (Table 4.3). These included two actin homologues (Smp_183710 and Smp_046600), two tegument allergen-like proteins (Smp_086480 and Smp_077310) and two tubulin chains (Smp_103790 and Smp_192110) (Table 4.3). In contrast, the genes coding for an endothelin 2 homologue (Smp_122030) and an endothelin-converting protein (Smp_159370) were up-regulated.

Table 4.3: A list of all genes differentially expressed between the RNA-seq samples of paired and separated males at day 8 after perfusion. The average read counts provide a measure of absolute expression for a given gene. The fold changes reflect expression in separated males relative to paired males. That means fold changes greater than 0 are up-regulated separated males, and those smaller than 0 are down-regulated in separated males. The $p$-value has been adjusted for multiple hypothesis testing.

### 4.2.6 Time series analysis

## Female Time Series Analysis

The pairwise comparison of females RNA-seq samples at day 8 was noisy and highly enriched for ribosomal and mitochondrial genes. To overcome this problem, I analysed a time-series that combined the data of all female samples over the whole time course of day 0,4 and 8 . The aim was to generate a more accurate list of differentially expressed genes. This approach should allow for a better estimate of variation between biological replicates as well as between treatment groups and yield more statistical power to identify differentially expressed genes.

Figure 4.8: In this Principal component analysis plot female samples separate by time, but not pairing status. This is a PCA plot of a time series analysis of female samples at 0,4 and 8 days after perfusion. The PCA shows high variance between the separated females at day 8 after perfusion, but paired and separated samples overlap and do not separate into distinct groups.

By using a likelihood ratio test, genes were identified that were expressed in a pairing specific manner (Table 4.4). Paired and separated females at day 0 , where no differences should be observed, were used to control for differences between the groups at the later time points. The day 0 samples are also compaired against later time points to identify changes in gene expression over time. Out of 10439 genes with non-zero read counts, 9848 (94\%; mean expression cut-off of fewer than 6545 reads) were filtered out by the DESeq2 independent filtering algorithm, 52 were removed as outliers and in total 103 DEGs were identified (adjusted p-value > 0.1), one of which was up-regulated in paired females. The remaining 102 DEGs were up-regulated in separated females (Table 4.4). As in the previously described pair-wise analysis, Smp_049270 (coding for the major egg antigen) was up-regulated in paired females ( p -value $=$
0.017 ) but the number of genes up-regulated in separated females was $30 \%$ smaller compared to the pair-wise comparison (103 compared to 150 DEGs).

| Gene ID | Average <br> read count | Fold <br> change | Adjusted <br> p-value | Product |
| :--- | ---: | ---: | ---: | :--- |
| Smp_000280 | 17110.6 | 3.16 | 0.017 | Trematode eggshell synthesis domain <br> containing protein |
| Smp_000390 | 7664.0 | 3.36 | 0.017 | Trematode eggshell synthesis domain <br> containing protein |
| Smp_000420 | 17283.8 | 3.18 | 0.017 | Uncharacterised protein |
| Smp_000430 | 45222.4 | 3.61 | 0.017 | Trematode eggshell synthesis domain |

Table 4.4: Table of the $\mathbf{2 5}$ most differentially expressed genes identified in the female time series analysis. The average read counts provide a measure of absolute expression for a given gene. The fold changes provided are expression at day 8 in separated females relative to paired females. That means fold changes greater than 0 are up-regulated separated females, and those smaller than 0 are down-regulated in separated females. The $p$-value has been adjusted for multiple hypothesis testing.

The DEGs up-regulated in separated females still included a large number of fertitlity-related genes, such as genes coding for trematode eggshell synthesis domain containing proteins and an extracellular superoxide dismutase (Table 4.4). Furthermore, many ribosomal and mitochondrial genes were up-regulated in separated females compared to paired females. This resembles the results from earlier comparison of paired and separated females at day 8 (Chapter 4.2.4). The greatest factor influencing the transcriptome of these worms is certainly the time spent in vitro, as indicated by the results in Chapter 3.2.11 as well as the PCA plot (Figure 4.4). Together with the great variability in gene expression found in the separated females (see Figure 4.6), this may explain these unexpected results to some extend.

## Male Time Series Analysis

The PCA plot (Figure 4.9) revealed that the variability of the biological replicates increased over time. Out of 10336 genes with non-zero read counts, none were filtered out by the DESeq2 independent filtering algorithm, compared to the $94 \%$ of genes filtered out in the female time series analysis (94\%) as a result of lower overall variability across biological replicates. No genes were identified to be outliers based on the Cook cut-off. Using the same threshold for significance as for the female samples (adjusted p-value < 0.1) 23 genes were significantly upregulated in separated males and 25 up-regulated in paired males.

Among the up-regulated DEGs in paired males was a genes coding for the serine:threonine kinase VRK1 (Smp_141380, 1.2x change, adjusted p-value = $0.084)$ (Table 4.5), which is known to be involved in regulating proliferation of
reproductive tissues in schistosomes (Vanderstraete et al., 2014). Also upregulated were genes coding for a tyrosine phosphatase receptor (Smp_156870, 1.34 x change, adjusted p -value $=0.004$ ) as well as a DPY-30 homologue (Smp_026440, 1.8x change, adjusted p-value $=0.025$ ) (Table 4.5).

Figure 4.9: In this Principal component analysis male RNA-seq samples do not separate by pairing status. This is a PCA plot of the time series analysis of male samples at 0,4 and 8 days after perfusion. The PCA shows more variance between samples at day 4 and especially day 8 when compared to the day 0 samples.

Genes expressed significantly higher in separated males included genes coding for a tetraspanin (Smp_152990, 1.69x change, 0.024) and a spermatogenesis associated protein homologue (Smp_145360, 1.93x change, 0.030) (Table 4.5), a protein that in humans is needed for production of healthy spermatocytes (Bornstein et al., 2011). Furthermore, two signalling related genes were found up-regulated (Table 4.5), coding for a putative glypican homologue
(Smp_245810, 1.6x change, adjusted p-value $=0.030$ ), a group of heparin sulphate proteoglycans that regulate developmental pathways including Wnt (Filmus et al., 2008), and a delta-like protein D homologue (Smp_135370, 3.3x change, adjusted p -value $=0.089$ ), which is a member of the Notch signalling pathway (Gray et al., 1999). The Notch and Wnt signalling pathways both play crucial roles in the regulation of cell fate determination in animal development (Collu et al., 2014).

| Gene ID | Average <br> Read <br> Count | Fold <br> change | Adjusted <br> p-value | Product |

|  |  |  |  |  |

Table 4.5: The 25 most differentially expressed genes of the male time series analysis of paired and separated males at 0,4 and 8 days after perfusion. The average read counts provide a measure of absolute expression for a given gene. The fold changes are provided for the expression in separated males relative to paired males. That means fold changes greater than 0 are upregulated separated males, and those smaller than 0 are down-regulated in separated males. The $p$-value has been adjusted for multiple hypothesis testing.

I decided to also include in my thesis an analysis of the transcriptome changes that take place in male and female worms over the course of 8 days, grown in vitro, and how these changes relate to sexual regression, nutrient metabolism and other aspects of worm biology affected by the in vitro culture. For this
comparison samples of paired females at day 8 were used as they were shown to have relatively less variability across biological replicates compared to separated females (see Figure 4.5).

### 4.2.7 Comparison of females before and after in vitro culture

After 8 days, females in in vitro culture differentially expressed hundreds of genes compared to their day 0 counterparts, which were placed in Trizol immediately after perfusion and thus did not experience in vitro culture. Out of 10498 genes with non-zero read counts, DESeq2 filtered out 472 (4.5\%) genes with a mean expression of fewer than 1.1 reads and 105 outliers were identified using the default Cook cut-off of DESeq2 and subsequently removed from the analysis. This reflects the relatively lower variability in these samples compared to the separated females (D8FS) where $94 \%$ of genes were filtered out. Of the remaining genes 696 (6.4\%) were significantly down-regulated and 778 (7.2\%) up-regulated, after 8 days in vitro (adjusted p-value $<0.01$ ) (Fig 4.10).

Figure 4.10: In vitro culture of Schistosoma mansoni induces a great magnitude of changes in gene expression in female worms. Pair-wise comparison of female worms at day 0 and day 8 after perfusion. A) A plot of the log ratio against the mean expression showed a large numbers of genes significantly up-regulated (red) in both groups with large fold changes. Triangles indicate genes outside the boundaries of the plots; like other genes, they are red if they are statistically significant, grey if they are not. B) The principal component analysis shows that females samples separate well into two groups based on principal component 1 ( $57 \%$ of observed variance). These results demonstrate the significant effect of in vitro culture on the female transcriptome.

Among the most down-regulated genes were several coding for proteins that are important for digestion, in particular lysosomes, such as saposin-related proteins, a lysosomal Pro-X carboxypeptidase and cathepsin B (Table 4.6). These proteins help to break down macromolecules such as proteins and lipids taken up in autophagic or phagocytic vacuoles to make these nutrients available to the cell metabolism (Luzio et al., 2007). Other down-regulated genes included those coding for the transmembrane protein 60,2 zinc finger proteins, a nogo $B$ receptor homologue and a parathyroid hormone 2 receptor (Table 4.6).

Both CD63 genes that were found to be significantly up-regulated in mature, paired females in the previous chapter - Smp_173150 \& Smp_155310 - were found to be significantly down-regulated in females after in vitro culture. Smp_173150 was 5.35 x down-regulated (adjusted p -value $=9.21 \mathrm{E}-11$ ) and Smp_155310 was 6.27x down-regulated (adjusted p-value $=0.00026$ ) (Table 4.6). These results are similar to those from the RNAi experiment in Chapter 3 where in vitro culturing was found to lead to a significant down-regulation of the CD63 receptor and antigen transcripts. The lower p-value of Smp_155310 compared to Smp_173150 is the result of lower expression levels of Smp_155310 ( $\sim 40 \%$ of the expression level of Smp_173150; see Table 4.6).

KEGG pathway enrichment analysis showed that the lysosome (smm04142) was the most significantly down-regulated of 14 pathways involving the metabolism of different amino acids, lipids and carbohydrates (Table 4.7). The second most significantly down-regulated pathway was sphingolipid metabolism (smm00600; p-value $=0.002$ ): the genes coding for ceramide synthase (Smp_042440) and ceramide kinase (Smp_130110) were down-regulated 2.54x (adjusted p-value $=1.03 \mathrm{E}-06$ ) and $2.06 x$ (adjusted $p$-value $=2.91 \mathrm{E}-10$ ) respectively (Table 4.6).

Pfam domain enrichment (Table 4.8) revealed a striking down-regulation of genes coding for proteins with trematode eggshell synthesis domains, with 10 out of 11 genes containing such a domain being down-regulated after eight days outside the host ( p -value $=2.05 \mathrm{E}-11$ ), which is consistent with a decline of egg being laid in vitro and a reduction in the expression of associated genes that has
been observed before (Galanti et al., 2012). Smp_000430, the only gene of this group not to be down-regulated significantly, fell narrowly short of the significance threshold (adjusted p -value $=0.013$ ) despite a 3.7 x reduction of expression (Table 4.6). Across all of the differentially expressed genes found in this comparison of females before and after 8 days in in vitro culture, the downregulation of genes coding for trematode egg shell synthesis domain-containing genes (Table 4.7) is the most compelling evidence that reproductive activity is being shut down in these females.

| Gene ID | Average <br> read count | Fold <br> change | Adjusted <br> p-value | Product |
| :--- | ---: | ---: | :--- | :--- |
| Smp_181070 | 25744.6 | 11.15 | $1.24 \mathrm{E}-35$ | Uncharacterised protein |

| Smp_130110 | 1423.8 | 2.09 | $2.91 \mathrm{E}-10$ | Ceramide kinase |

Table 4.6: A selection of significantly down-regulated genes from the comparison of female Schistosoma mansoni at day 8 compared to day 0 in vitro. This table contains the 20 most significantly down-regulated genes as well as those specifically mentioned in the results. The average read counts provide a measure of absolute expression for a given gene. The fold changes are the gene expression at day 8 relative to day 0 . The $p$-value has been adjusted for multiple hypothesis testing.

| KEGG ID | Pathway | Significant <br> Genes | Total <br> Genes | p-value |
| :--- | :--- | ---: | ---: | ---: |
| smm04142 | Lysosome | 15 | 47 | $1.66 \mathrm{E}-05$ |
| smm00600 | Sphingolipid metabolism | 6 | 15 | $1.72 \mathrm{E}-03$ |

| smm00053 | Ascorbate and aldarate metabolism | 2 | 4 | $4.71 \mathrm{E}-02$ |
| smm00360 | Phenylalanine metabolism | 2 | 4 | $4.71 \mathrm{E}-02$ |

Table 4.7: KEGG pathways enriched amongst the significantly downregulated genes in females at day 8 after perfusion compared to females at day $\mathbf{0}$ females. The column "Significant Genes" provides the number of genes in a given pathway that were down-regulated in day 8 females; "Total Genes" is the total number of genes in the pathway.

| Pfam ID | Domain | Significant <br> Genes | Total <br> Genes | p-value |
| :--- | :--- | ---: | ---: | ---: |
| PF08034 | Trematode eggshell synthesis protein | 10 | 11 | $2.05 \mathrm{E}-11$ |
| PF00112 | Papain family cysteine protease | 9 | 16 | $2.09 \mathrm{E}-07$ |
| PF00255 | Glutathione peroxidase | 3 | 3 | $3.15 \mathrm{E}-04$ |
| PF01008 | Initiation factor 2 subunit family | 3 | 3 | $3.15 \mathrm{E}-04$ |
| PF03982 | Diacylglycerol acyltransferase | 3 | 3 | $3.15 \mathrm{E}-04$ |
| PF04261 | Dyp-type peroxidase family | 3 | 3 | $3.15 \mathrm{E}-04$ |
| PF03062 | MBOAT, membrane-bound O-acyltransferase | 4 | 8 | $1.13 \mathrm{E}-03$ |
| PF08127 | family | 3 | 4 | $1.17 \mathrm{E}-03$ |
| PF00106 | Short chain dehydrogenase | 7 | 27 | $1.45 \mathrm{E}-03$ |
| PF00789 | UBX domain | 3 | 5 | $2.74 \mathrm{E}-03$ |

Table 4.8: A table of the 10 Pfam domains found to be most significantly enriched among the genes which were down-regulated in females on day 8 after perfusion compared to females day 0 . The column "Significant Genes" provides the number of genes encoding a given domain that were downregulated in day 8 females; "Total Genes" is the total number of S. mansoni genes containing the domain.

Among the most up-regulated DEGs (Table 4.9) were several genes coding for proteins with proteolysis related functions such as E3 ubiquitin protein ligase and the peptidase inhibitor 16. Another gene, coding for an S 9 family nonpeptidase homologue, was also found up-regulated although, as the name suggests, it does not have peptidase activity. Furthermore genes coding for a DC STAMP domain protein, otopetrin, and sortilin were up-regulated as well as many cell adhesion related proteins including innexin and protocadherin 1.

An analysis of KEGG pathways showed extracellular matrix (ECM) receptor interactions to be the most significantly up-regulated pathway after 8 days (pvalue $=0.00013$ ). The analysis also showed that many genes coding for protein domains associated with the ECM were expressed at higher frequency than expected by chance. This included genes coding for proteins with the following domains: cadherin ( $p$-value $=1.38 \mathrm{E}-13$ ), laminin N -terminal $(\mathrm{p}$-value $=0.0053)$, laminin G (p-value $=0.013$ ), annexin ( $p$-value $=0.017$ ), and fibronectin type III ( p -value $=0.024$ ). The above pathways are summarised in Table 4.10.

Pathway analysis further showed up-regulation of developmental signalling pathways, such as the Jak-STAT, Wnt, Notch, mTOR, FoxO and Hedgehog signalling pathway as well as neuroactive ligand-receptor interactions after 8 day in vitro (Table 4.10). Neural processes are involved in the maintenance of the female germline (Collins et al., 2010) and their differential expression in this experiment may be further evidence for that function. Furthermore the analysis of Pfam domains showed that genes coding for proteins with several closely related epidermal growth factor (EGF) domains were up-regulated at a higher
frequency than expected by chance. These included a total of 16 genes (Table 4.11). Up-regulation of growth factors was unexpected because these females were thought to be in the process of reducing their reproductive capacity, particularly egg production. Out of the 16 up-regulated genes with EGF domains, eight are involved in extracellular matrix receptor interactions, the pathway most significantly enriched with genes up-regulated in day 8 females (Table 4.10). These protein products of these genes play an important role in tissue remodelling and the regulation of cell survival (Gray et al., 1999). Of the remaining eight genes, five code for neurogenic locus notch proteins, members of the significantly up-regulated notch signalling pathway (Table 4.10). Notch proteins are a group of proteins thought to be essential for maintenance of neuronal progenitor cells as well as neurogenesis (Zhou et al., 2010). In total eight neurogenic locus notch proteins are annotated in the Schistosoma genome, five of them are differentially up-regulated after 8 days in vitro and the remaining 3 are not differentially expressed (Table 4.9). The Pfam domain enrichment analysis revealed another group of genes with neural related functions called semaphorins to be up-regulated significantly (Smp_159050, 1.89 x change, adjusted p -value $=0.00053$; Smp_158550, 1.4 x change, adjusted p value $=0.028 ;$ Smp_132520, 6.97x change, adjusted $p$-value $=1.22 \mathrm{E}-07)($ Table 4.9). These genes encode proteins that are either membrane bound or secreted and act as inhibitors of axon growth, thus helping to regulate neurone development (Bashaw \& Klein, 2010). In addition to the semaphorin genes a homologue of the SLIT gene was up-regulated in these female worms (Smp_147470, 2.30x change, adjusted p-value $=0.0013$ ) (Table 4.9), which also regulates axon growth in D. melanogaster and H. sapiens (Bashaw \& Klein, 2010).
change, adjusted $p$-value $=2.89 \mathrm{E}-08$; Smp_028030, 1.88 x change, adjusted p value $=7.21 \mathrm{E}-05$ ) were also up-regulated. Furthermore, the significantly upregulated Wnt signalling pathway (Table 4.10), is known to help establish a growth axis within developing axons (Mulligan \& Cheyette, 2012).

Figure 4.11: Many genes involved in axon development became upregulated in vitro. Heatmap of neurogenesis related genes in female worms at day 0 (three replicates: D0 F1-3) and day 8 (four replicates: D8 F1-4). Colours represent a Z score of log transformed normalised read counts scaled by row, giving relative measures of gene expression in each sample. Average normalised read counts for each gene are in the row on the right on a logarithmic scale as a measure of absolute expression levels.

Several other groups of genes involved in the regulation of axon development were found to be expressed differently at day 8 , including genes coding for netrins, netrin receptors, a plexin homologue, ephrins and their receptors, a slit robo homologue and a catenin delta homologue (Fig. 4.11), which play important roles in the guidance, pruning and deletion of axons, in some case regulated by the Wnt pathway (Bashaw \& Klein, 2010; Vanderhaeghen \& Cheng, 2010). In the heat map of neurogenesis related genes, samples clustered well by treatment but also revealed variability between biological samples (Fig. 4.11). Overall Fig. 4.11 shows a trend of genes coding for proteins involved in the processes of axon guidance and axon pruning to be expressed at higher levels at day 8 (for example ephrin and the ephrin receptors, netrins and their receptors, slit and ROBO as well as semaphorins, plexins and neurophilins (Bashaw \& Klein, 2010)). In contrast, several genes known to be critical for neuron survival, such as survival of motor neuron 1 and fragile X mental retardation protein 1 as well as proteins interacting with them can be seen to be down-regulated at day 8 in Fig. 4.11.

Work by Galanti et al. (2012) showed that females begin to regress to a sexually immature state once removed from the mammalian host and that the rate of apoptosis increases, resulting in the reduction of reproductive tissue, especially in the vitellarium. A small number of the apoptosis related genes discussed at the beginning of this chapter were found to be differentially expressed in the female worms. Two genes coding for the $\mathrm{Bcl}-2$ domain containing protein (Smp_043360) and the FAS associated factor 2 (Smp_084610) were found to be down-regulated after day 8 (Table 4.9). In contrast, two genes were found to be up-regulated in females after in vitro culture (Table 4.9): the genes coded for the

FAS associated factor 1 (Smp_077540), and the FAS binding factor 1 (Smp_148130). However, overall there was no clear pattern of up- or downregulation of apoptosis related genes, one of the samples of female worms at day 0 did not even cluster with the other day 0 samples (Fig. 4.12).

Figure 4.12: No clear trend was found in the expression of pro- and antiapoptotic genes. Heatmap of apoptosis related genes in females Schistosoma mansoni at day 0 (three replicates: D0 F1-3) and day 8 (four replicates: D8 F1-4). Colours represent a Z score of log transformed normalised read counts scaled by row, giving relative measures of gene expression in each sample. The " + " and "-" to the right of the heat map indicate putative pro- and anti-apoptotic function; apoptosis related genes whose exact role could not be determined are marked "?".

Although a heat map of the apoptosis related genes and their expression in females at day 0 and 8 showed some consistent patterns, one of the day 0 females did not cluster with the others nor did a trend for pro- or anti-apoptotic genes to be expressed in either group become apparent (Fig. 4.12).

Table 4.11: Pfam domains which were significantly enriched amongst the genes up-regulated in females at day 8 after perfusion compared to females at day $\mathbf{0}$. The column "Significant Genes" provides the number of genes encoding a given domain that were up-regulated in day 8 females; "Total Genes" is the total number of Schistosoma mansoni genes encoding the domain.

### 4.2.8 Comparison of males before and after in vitro culture

The comparison of day 0 and day 8 was performed for male worms as well, revealing transcriptome changes of a similar magnitude as in the female comparison. After removing 962 (9.2\%) genes with low read counts and 105 (1\%) outliers it was found that 493 (4.6\%) genes were down-regulated and 717 (6.6\%) genes up-regulated after 8 days in culture (adjusted p-value $<0.01$ ) (Figure 4.13 A ). As the MA plot revealed, the fold changes observed in males were relatively small compared to those in females (compare Figure 4.10 A and 4.13 A). The first two principal components, shown in the PCA plot, explain 72\% of variability measured across the samples (Figure 4.13 B).

Figure 4.13: In vitro culture induced large changes in gene expression in male worms. Pair-wise comparison of male worms at day 0 and day 8 after perfusion. A) The log ratio against mean (MA) plot shows large numbers of genes significantly up-regulated (red) in both groups with large fold changes. Triangles indicate genes outside the boundaries of the plots; like other genes, they are red if they are statistically significant, grey if they are not. B) Principal component analysis shows that males samples also separate well into two groups based on principal component 1 ( $53 \%$ of observed variance). These results demonstrate a significant effect of in vitro culture on the male transcriptome.

Of the 717 genes up-regulated at day 8 , the most significantly differentially expressed gene coded for a homologue of the interferon-related developmental regulator (Smp_004680; 2.13x change; adjusted p-value $=4.60 \mathrm{E}-17$ ) (Table 4.12). Also differentially expressed were genes coding for a phenylalanyl-tRNA synthase $\beta$ (Smp_094060; 1.41x change; adjusted $p$-value $=4.69 \mathrm{E}-17$ ), a heat shock 70 protein (Smp_106930; 2.91x change; adjusted p-value $=4.21 \mathrm{E}-14$ ) ) and a $\gamma$-secretase subunit APH (Smp_050110;1.83x change; adjusted p-value $=4.31 \mathrm{E}$ 13) as well as many proteins with unknown function (Table 4.12).

After 8 days four pathways were significantly down-regulated in male worms (pvalue $<0.05$ ) compared to males at day 0 (Table 4.13). Down-regulation of RNA transport ( $\mathrm{smm} 03013 ; p=0.0049$ ), mRNA surveillance ( $\mathrm{smm} 03015 ; \mathrm{p}=0.028$ ), and protein processing in endoplasmic reticulum (smm04141; $\mathrm{p}=0.039$ ) suggested a down-regulation of transcription. Also down-regulated was N Glycan biosynthesis (smm00510; p = 0.034), which plays a role in the posttranslation modification of glycoproteins (Bieberich, 2014). Furthermore, the Pfam domain enrichment analysis (Table 4.14) suggested that in addition to RNA processing, many genes coding for proteins with DNA replication and cell cycle control related function were down-regulated after 8 days outside the host. These relevant domains include MIF4G domain (PF02854; p = 0.0010), which forms part of translation initiation factors (Virgili et al., 2013); Rad17 cell cycle checkpoint domain (PF03215; p = 0.0024), involved in cell cycle control (Post et al., 2003); and BRCA1 C Terminus domain (PF00533; $\mathrm{p}=0.0072$ ), which occurs in proteins that help to regulate the cell cycle in response to DNA damage (Deng, 2006). Also significantly down-regulated were genes coding for several heat
shock protein associated domains, including Hsp20 crystalline family (PF00011; $\mathrm{p}=1.69 \mathrm{E}-07$ ), DnaJ central domain (PF00684; $\mathrm{p}=0.0024$ ), Dnaj C terminal domain (PF01556; p = 0.013) and Hsp70 domain (PF00012; p = 0.039). Finally, GO term enrichment analysis showed, among others (Table 4.15), DNA replication (GO:0006260, p-value $=5.30 \mathrm{E}-05$ ), cell division (GO:0051301, pvalue $=0.0020$ ), meiotic nuclear division (GO:0007126, $p$-value $=0.0056$ ) and cell cycle (GO:0006269, p-value $=0.012$ ) down-regulated, suggestion a reduction in sperm production as well as somatic cell division.

| Gene ID | Average <br> Read Count | Fold Change | p-value | Product |
| :--- | ---: | ---: | ---: | :--- |

Table 4.15: GO terms which were significantly enriched amongst the downregulated genes in males at day 8 after perfusion compared to males at day
0. The column "Significant Genes" provides the number of genes associated with a given GO term that were down-regulated in males at day 8; "Expected Genes" provides the number of up-regulated genes annotated with the GO term as expected by chance. The GO terms are all in the "Biological Process" category.

The most up-regulated genes (Table 4.16) included several genes coding for proteins with neural function. This included a netrin homologue (Smp_146840, 5.62 x change, adjusted p -value $=1.67 \mathrm{E}-20$ ), and a catenin delta- 2 homologue (Smp_042340, 3.04 x change, adjusted p -value $=1.64 \mathrm{E}-13$ ), both of which are thought to play important roles in neural development (Bashaw \& Klein, 2010). Also up-regulated were genes coding for a stomatin homologue (Smp_003440, 5.72 x change, adjusted p -value $=1.97 \mathrm{E}-16$ ), a neurogenic locus Notch protein homologue (Smp_143300, 7.58x change, adjusted p-value 2.12E-16) and a calcium binding protein that confers elasticity to the ECM (Handford, 2000). Another up-regulated gene codes for a RNA polymerase associated factor 1
homologue (Smp_045940, 2.15x change, 2.52E-13), which is a component of the PAF1 complex that is thought to regulate development and maintenance of embryonic stem cell pluripotency in humans (Ding et al., 2009). Also among the ten most differentially expressed genes are three genes with unknown function (Table 4.16).

| Gene ID | Mean Read <br> Count | Fold change | Adjusted <br> p-value | Product |

Table 4.16: Selection of the genes significantly up-regulated in males at day 8 after perfusion compared to males at day 0 . Average read counts provide a measure of absolute expression for a given gene. Fold changes represent the gene expression in males at day 8 after perfusion relative to day 0 . The $p$-value has been adjusted for multiple hypothesis testing.

After 8 days in vitro the up-regulated genes were enriched for pathways such as citrate cycle (smm00020; $p=0.00086$ ), neuroactive ligand-receptor interaction (smm04080; $p=0.0044$ ), wnt signalling pathway (smm04310; $p=0.0049$ ), ECMreceptor interaction (smm04512; $\mathrm{p}=0.0072$ ), as well as two amino acid metabolism pathways (smm00330; p = $0.0084 \& s m m 00250 ; p=0.024$ ) (Table 4.19). Three out of the six significantly up-regulated pathways in male worms were also up-regulated in female worms after 8 days: the neuroactive ligandreceptor interaction, the wnt signalling pathway and the ECM-receptor interaction (Tables 4.10 and 4.19).

After 8 days in culture, the up-regulated DEGs were enriched with genes coding for domains such as the neurotransmitter-gated ion-channel ligand binding domain (PF02931; $\mathrm{p}=0.00021$ ), the neurotransmitter-gated ion-channel transmembrane region (PF02932; $\mathrm{p}=0.00068$ ) and several EGF-related domains (as observed in the female worms; Table 4.11), including the calciumbinding EGF domain (PF07645; p = 0.0016), EGF-like domain (PF00008; p = 0.0064) and laminin EGF-like (Domains III and V) (PF00053; p = 0.017), in total ten genes with EGF domains (Table 4.17). Many of the genes up-regulated in males were involved in neural processes (Table 4.16). The annotation of the following genes was confirmed by checking for relevant PFAM domains as well as significant BLAST hits (data not shown here). They include a genes coding for a neurogenic locus notch protein (Smp_140800, 1.63x change, adjusted p-value $=$ 0.0065 ), thought to be involved in neural cell progenitor maintenance (Louvi \& Artavanis-Tsakonas, 2006), two homologues of netrin (Smp_146840, 5.62x change, adjusted p-value = 3.53E-24; Smp_151310, 3.37x change, adjusted p-
value $=5.01 \mathrm{E}-05$ ), a gene involved axon guidance (Bashaw \& Klein, 2010), and agrin (Smp_155050, 2.27x change, adjusted p -value $=1.83 \mathrm{E}-05$ ), a large proteoglycan thought to play a role in the development of neuromuscular junctions (Bolliger et al., 2010) and finally genes coding for a homolog of neurexin-2 (Smp_123860, 2.75x change, adjusted p-value = 0.00076) and a neuronal cell surface protein that mediates the assembly of presynaptic terminals (Dean et al., 2003). In addition to the genes of both netrin homologues in the $S$. mansoni genome being up-regulated in male worms after 8 days, all three genes coding for homologues of the netrin receptor were also up-regulated in these worms (Smp_157620, 3.26x change, adjusted p-value = 3.24E-09; Smp_172470, 2.25 x change, adjusted p-value $=8.39 \mathrm{E}-05$; Smp_165440, 2.12 x change, adjusted p -value $=4.57 \mathrm{E}-08$ ). One other gene annotated as a netrin receptor homologue on GeneDB, Smp_080870, was found not to contain any conserved domains nor to have BLAST hits to relevant proteins and was excluded from this analysis. The gene coding for slit (Smp_132540, 1.97x change, $\mathrm{p}=0.0014$ ), another regulator of axon guidance (Bashaw \& Klein, 2010), was also up-regulated in the male worms after 8 days, as was the gene of a semaphorin homologue (Smp_159050, 2.08x change, adjusted p-value $=2.98 \mathrm{E}$ 06) (Table 4.16).

GO term enrichment (Table 4.18) showed GO terms related to cell adhesion to be most significantly enriched (G0:0007155, p-value $=1.90 \mathrm{E}-17$; GO:0007156, p value $=2.00 \mathrm{E}-13$ ), but also several development and regulatory GO terms to be up-regulated. These include G-protein coupled receptor signalling (G0:0007186, p-value $=5.20 \mathrm{E}-06$ ), multicellular organismal development (GO:0007275, p-
value $=0.00031$ ), negative regulation of cell differentiation (GO:0045596, pvalue $=0.00043$ ) and negative regulation of BMP signalling (GO:0030514, pvalue $=0.00043$ ) (Table 4.18). Furthermore, two pathways implicated in the development and growth of axons were found up-regulated. The first, Wnt signalling (GO:0016055, p-value $=0.0175$ ), helps to establish the body's axes in developing organisms including Schmidtea mediterranea (Gurley et al., 2010). Also up-regulated was gamma-aminobutyric acid (GABA) signalling (GO:0007214, p-value $=0.0162$ ), which has been shown to play a role in axon pruning in mice (Wu et al., 2012). The heat map of neurogenesis related genes (Figure 4.14) contains genes identified from the differential expression analysis as well as from the literature by including differentially expressed homologues of genes discussed by Bashaw \& Klein (2010) and Vanderhaeghen \& Cheng (2010). It showed that both male and female worms exhibited similar trends in gene expression (Figure 4.11). Genes coding for netrin and netrin receptor genes, as well as slit, ephrin receptor, semaphorin and plexin genes were up-regulated after 8 days in vitro. On the other hand, neuron survival genes such as genes coding for FXMR, SMN as well as most catenin genes were not differentially expressed, or even slightly down-regulated (Figure 4.14). Although this overall trend held true, and samples clustered well by treatment, variability within biological replicates could be clearly seen.

Figure 4.14: Axon proning-related genes became up-regulated in vitro. Heatmap of neurogenesis related genes in males worms at day 0 (five replicates: D0 M1-5) and day 8 (seven replicates: D8 M1-7). Colours represent a Z score of log transformed normalised read counts scaled by row, giving relative measures of gene expression in each sample. Average normalised read counts for each gene are in the row on the right on a logarithmic scale as a measure of absolute expression levels.

Unlike in female worms, no large changes in the set of apoptosis related genes were expected, as male worms are generally thought to remain sexually mature in the absence of a partner (Basch, 1991). The heat map of apoptosis related genes in male worms (see Figure 4.15) suggested that only small changes in the transcription of these genes took place between day 0 and 8 in culture, but no clear pattern of differential expression of pro- or anti-apoptotic genes emerged.

In total, nine out of 27 genes were differentially expressed (Table 4.20). This included four genes - two pro-apoptotic and two with unknown effect - downregulated after 8 days and five genes up-regulated - three anti-apoptotic and two pro-apoptotic genes.

However, the fold changes were relatively small (Table 4.20). These data suggested that there is regulation of apoptosis at the transcriptome level. However, it did not conclusively indicate apoptosis being up-regulated during in vitro culture. Apoptosis after 8 days was expected to take place at a lower rate compared with females due to regression of the reproductive tissues taking place in females (Galanti et al., 2012). However, due to high levels of variability, increased apoptosic activity could not be demonstrated for female worms.

Figure 4.15: Expression of apoptosis-related genes does not show clear trends before and after in vitro cultrue. No Heatmap of apoptosis related genes in males worms at day 0 (five replicates: D0 M1-5) and day 8 (seven replicates: D8 M1-7). Colours represent a Z score of log transformed normalised read counts scaled by row, giving relative measures of gene expression in each sample. The " + " and "-" to the right of the heat map indicate putative pro- and anti-apoptotic function; apoptosis related genes whose exact role could not be determined are marked "?".

| Pfam ID | Domain | Significant <br> Genes | Total <br> Genes | p-value |

Table 4.20: Table of apoptosis-related gene expression in the comparison of male Schistosoma mansoni after 8 days in vitro. Average read counts provide a measure of absolute expression for a given gene. Fold changes express the gene expression at day 8 relative to day 0 . The $p$-value has been adjusted for multiple hypothesis testing.

### 4.3 Discussion

## Pairing-specific changes in gene expression are obscured by the effect of in vitro cultivation on the transcriptome

Maintenance of $S$. mansoni in vitro has been noted in the past to have adverse effects on female fertility (Basch, 1991) and regression of female reproductive tissue has been observed in the presence and absence of male worms (Galanti et al., 2012). To optimally support female fertility in in vitro culture, Basch medium was tested here for the maintenance of $S$. mansoni in vitro. It was found to support female fertility to a significantly greater extent than a less rich medium. Overall females were found to lay six times as many eggs over four weeks in Basch medium. Supplementation of the growth media with red blood cells was also shown to have a significant effect on fertility, resulting in a 2-fold increase of egg production in media supplemented with $1 \%$ RBC compared to media without RBC.

The next challenge was the isolation of sufficient total RNA from single worms to prepare cDNA libraries. Using an extraction protocol that I had optimised (Chapter 2.2.3) at least 50 ng of total RNA could be isolated from 60 single worm samples. From the generated RNA-Seq data, 150 genes were identified to be differentially expressed between paired and separated females after 8 days in culture and 42 in between paired and separated males. Even more genes were identified to be differentially expressed in comparisons of worms before and after in vitro culture, 1474 DEGs in female worms and 1210 in males.

A considerable problem in this analysis was the large variability in gene expression between biological replicates, particularly of female worms. This made it very difficult to examine the effect of treatment, i.e., the pairing or separation of pairs. The magnitude of variability increased over the course of the experiment. The PCA plot of all samples (Figure 4.4) as well as the PCA plots of the time series analysis (Figure 4.8 and Figure 4.9) suggested that the effect of in vitro culture on the transcriptome was greater than of the treatment itself, despite the optimisation efforts. The in vitro culture of worms is a long established technique but one that has been noted to have significant draw backs and weaknesses, most notably the decline of female fertility but also slow or absent maturation of immature worms (Galanti et al., 2012). The variability within the biological replicates reduced the statistical power to detect differentially expressed genes and obscured the effect of unpairing on the transcriptome of worms, especially for genes with moderate to low expression. As a result fewer than expected differentially expressed genes, 150 DEGs in total, could be identified between paired and separated females. Furthermore these results included several unexpected genes, including those coding for putative fertility-related proteins (eggshell protein, Smp_000430; and eggshell synthesis domain containing protein, Smp_077890) being up-regulated in separated females compared to their paired counter parts at day 8. Had the effects of in vitro culture been smaller, more subtle effects could have been identified in the separated females. The process of sexual regression that female worms undergo when removed from their mate should ideally be studied in vivo to ensure proper host condition. This could be achieved by perfusing worms from mixed sex infections, isolating mature females and reimplanting them into a new host
before perfusing them again after a few days or weeks to extract the RNA of these separated worms from in vivo conditions. This method of reimplanting worms into a host surgically has been used in the past (e.g. Basch 1990). However, this would be an invasive procedure that could cause injury and stress to the female worms, and likely impact their transcriptomes.

In male worms, only 42 DEGs were identified, all of which had relatively small fold changes, ranging from $1.8 x$ to $1.12 x$ with a median fold change of $1.3 x$. These fold changes are consistent with small changes in expression in the male worms but could also have resulted from larger fold changes in particular tissues. Such changes would become masked by measuring the average expression across whole male worms. The fact that DEGs were identified by DESeq2 in the comparison of male worms, despite the overall small fold changes, could indicate that the relatively low number of DEGs in the female comparison could be due to high levels of variability across biological replicates. In male worms on the other hand, there seems to be genuinely low levels of differentially expressed genes.

Down-regulation of genes coding for two actin homologues, two tegument allergen-like proteins and two tubulin genes, would indicate a reduction of the size of the tegument and muscle tissue. The up-regulation of a gene coding for an endothelin 2 homologue as well as an endothelin-converting protein suggests an involvement of this peptide hormone in the response of male S. mansoni to being separated from their partner. In humans, endothelin primarily plays a role in the regulation of blood pressure and has also been shown stimulate the nervous system (Bruno et al., 2011).

## Differential expression of apoptosis related genes does not conclusively show up or down-regulation

To study the role of apoptosis in regression of female reproductive tissues I carefully curated a list of 27 putative apoptosis-related genes, making sure that their gene models were supported by RNA-Seq evidence and that they had sufficient homology to known apoptosis effectors. The function as well as domain structure of these apoptosis-related genes is described in more detail in Appendix B. I was expecting to find pro-apoptotic genes to be up-regulated in separated females compared to paired females. However the comparison between paired and separated females did not provide conclusive evidence for up-regulation of apoptotic genes nor did the comparison of worms from day 0 and day 8 , although some differential regulation of apoptosis-related genes was observed. Again this may to have been due to the high degree of variability between biological replicates introduced by in vitro culture. Notably, sphingo lipid metabolism-related genes were found to be differentially expressed at a higher than expected rate. Sphingolipids are important components of membranes and help cells to withstand stress (Futerman \& Hannun, 2004). They can also be involved in signalling as is the case with ceramide. Ceramide is a sphingolipid and an important positive regulator of apoptosis (Thomas D Mullen \& Obeid, 2012; Tirodkar \& Voelkel-Johnson, 2012). Two genes have been shown to be of particular importance for controlling ceramide levels in cells: Ceramide kinase that phosphorylates ceramide, greatly diminishing its pro-apoptotic effect, and ceramide synthase that helps to synthesis ceramide and has a proapoptotic effect (Jensen et al., 2014). However, both genes coding for these protein were significantly down-regulated after in vitro culture. However, both
ceramide kinase and ceramide synthase were found to be down-regulated after in vitro culture. It was therefore not possible to reliably assess, whether the down-regulation of the sphingolipid metabolism pathway had a pro- or antiapoptotic effect. Overall, differential expression of apoptosis-related genes in a manner consistent with my pro- and anti-apoptotic classification could not be demonstrated although several of these genes were found to be differentially expressed.

## Neurogenesis related genes in male and female worms

One of the 42 DEGs in the comparison of paired and unpaired males was the gene coding for DYP-30 which was up-regulated in paried males. DPY proteins are involved in dosage compensation, but not sex determination, in C. elegans (Hsu \& Meyer, 1994) and the protein DPY-30 has recently been shown to be critical for neural lineage differentiation of mouse embryonic stem cells by regulating histone methylation (Jiang et al., 2011). Being located on the Z/W chromosome (Uniprot - G4VT64; https://www.uniprot.org/uniprot/G4VT64), it may play a similar role development of neural cells in S. mansoni.

However, the most striking finding was the differential expression of neurogenesis related genes in male and female worms, that suggested a regression of the nervous system during in vitro culture. As discussed in the introduction to this chapter, most of the genes involved in the process of neural development can function in several roles. In particular the ligand:receptor pairs known to control axon guidance, namely semaphorins and their plexin and neuropilin receptors, netrins and the DCC and UNC receptors, slit and its robo
receptors as well as ephrin and its receptors have also all been implicated in the pruning of axons and neural cell death (Vanderhaeghen \& Cheng, 2010). Notably, S. mansoni homologues of all of these genes were found to be differentially expressed after in vitro culture. Given the context of this data set and the well documented regression observed in worms outside the mammalian host, it seems most likely that the sudden up-regulation of these neural genes is correlated to a regression of parts of the schistosome nervous system. First and foremost several neuron survival genes are down-regulated at day 8 as can be seen from the heatmaps of both male and female worms (Figure $4.11 \& 4.14$ ). Secondly several further pieces of evidence point to this also, including the upregulation of GABA signalling in male worms at D8, which has been implicated in axon pruning, as well as the GO terms such as negative regulation of cell differentiation as well as the up-regulation of genes coding for neurogenic locus notch proteins in both male and female worms, a group of proteins thought to be essential for maintenance of neuronal progenitor cells. Combined, this evidence suggests that parts of the worm nervous system regresses by axon pruning and neural cell death and that neural progenitor cells are maintained in a undifferentiated form.

This process may be similar to the regression of reproductive tissues observed in female worms after they become separated from the male (Galanti et al., 2012). However, it was shown to be independent of worm gender as transcriptome changes consistent with neural regression were found in both males and females. As worms could not have evolved a response to in vitro culture, it seems likely that the regression was a response to the lack of a host factor. The host immune system is a plausible candidate, as schistosome development is known to be
modulated by B and T cells (Davies et al., 2001; Tang et al., 2013). Davies et al. (2001) found schistosomes derived from mice without B and T cells were smaller, uniform and undifferentiated at 26 days post infection compared to worms from wild type mice, and remained significantly smaller and stunted at 42 and 56 days after infection. Similar observations were made by Tang et al. (2013). The authors suggest that this may be a mechanism to ensure host and thus worm survival. Davies et al. (2001) speculated that by arresting worm development and thus temporarily preventing reproduction, host survival might be ensured, until the host is healthy enough again to sustain egg production. An important part of the $S$. mansoni nervous system is made up of the neuromuscular system. It allows the worms to control their movement, but also plays a role in digestion and excretion as well as other body functions (Ribeiro \& Patocka, 2013). During the process of regression any loss of muscle tissue would therefore likely be accompanied by a loss of neural cells involved on the neuromuscular processes. Like female worms regressing after becoming unpaired from the male worm, the neural regression observed here could be evidence that the immune system driven maturation is reversible in both genders.

## Chapter 5

## Exploration of the S. mansoni gonad transcriptome

### 5.1 Introduction

Schistosomes are a rare exception within the platyhelminths having evolved to be dioecious with distinct male and female individuals, however the sexual biology of schistosomes is not only of evolutionary interest but also a rich area of research. This is due to its potential as an intervention target in the Schistosoma life cycle as sexual reproduction is obligatory for schistosome reproduction but and because the eggs are essential for transmission and responsible most of the pathology caused by schistosomes (Gryseels, 2012). Few tissues play such a prominent role in reproduction as the testes and ovaries as they are responsible for generating the spermatocytes and oocytes required for fertilisation and the formation of embryos.

The gonads are highly specialised tissues in which cytokinesis takes place at a high rate and in which cells undergo meiosis (Beckmann et al., 2010). But not only are the tissues themselves specialised, they also produce specialised cells, the spermatocytes and oocytes. So it is to be expected that many genes will be uniquely expressed in the gonads or at least expressed differentially as compared to whole worms. In both genders the gonads make up a relatively small portion of the total organism, whereas the somatic worm tissues are comprised mostly of tegument, gut and muscle (especially in the male) and vitellarian tissue [in the female (Basch, 1990)].

The transcriptomes of both these organs have been examined in the past both in S. mansoni (Nawaratna et al., 2011) and S. japonicum (Gobert et al., 2009) using a
combination of laser micro dissection microscopy (LMM) and cDNA microarrays. These studies were great steps towards an improved understanding of the schistosome gonads but left room for improvement. The authors had to rely on less complete sequencing data as well as less up-to-date genome annotation for the construction of the microarrays. The study also lacked biological replicates and did not correct for multiple hypothesis testing. Nawaratna et al. (2011) found 1989 genes ( 4450 probes) to have at least 2 -fold higher expression in ovaries of mature females compared to a whole females, whereas 1188 genes (2171 probes) were found to have at least 2-fold higher expression in the testes of males from MS infections compared to control samples from whole MS males (Nawaratna et al., 2011). To explore the functional relationship between these genes, GO term enrichment analysis was performed. This gave a broad overview of the different groups of genes involved in processes such as "binding", "catalytic activity", "cellular process" and "metabolic process". However, as the annotation of the S. mansoni genome has been steadily improved since 2011 (Protasio et al., 2012), including the GO term annotation of genes, it is now possible to perform more in-depth enrichment analysis to yield greater insight into the underlying biological processes of sets of up- or down-regulated genes than was achieved previously.

Another aspect of gonad biology that so far has remained relatively unexplored is the transcriptome changes induced by pairing. Hahnel et al. (2013) developed a new method for the isolation of whole organs from S. mansoni using an approach that used both detergent and proteases to dissolve the outer layers of tegument and muscle to gain access to the worm gonads. This approach allowed
isolation of those tissues at a greater scale than previously feasible by micro dissection and thus made it possible to gather enough material for RNA sequencing. The team could demonstrate that cells could be isolated intact and with high quality RNA (Hahnel et al., 2013; Hahnel et al., 2014) and measured differential genes expression between the ovaries and testes of worms from mixed sex (MS) and single sex (SS), worms by qRT-PCR. Six genes putatively influenced by pairing based on transcriptomic evidence published in previous studies (Collins et al., 2013; Leutner et al., 2013; Zamanian et al., 2011) were chosen for closer examination: two genes coding for homologues of the fibroblast growth fator receptor (FGFR-A/B), and genes coding for one homologue each of frizzled (Fz1), membrane progestin receptor component 1 (PMRC1), notch and the RNA binding protein musashi. Most of the analysed genes were found to have up-regulated transcription upon pairing, supporting the hypothesis that these genes are regulated by pairing and play a role in the sexual maturation of females. While the authors demonstrated that high quality RNA can be extracted from the isolated gonads of S. mansoni, they did not show how the process of organ extraction effects the transcriptome (Hahnel et al., 2014).

The signalling network that regulates female fertility (see Figure 5.1) has been studied intensively (Beckmann et al., 2010; Knobloch et al., 2007; LoVerde et al., 2009; Andrade et al., 2014) and is described in Chapter 1.5. It comprises over 40 known genes, many of which have been characterised using in silico approaches, RNAi, in situ hybridisation, yeast-two-hybrid screens or using inhibitors such as herbimycin (Beckmann et al., 2010; Knobloch et al., 2006).

Figure 5.1: Representation of the MAPK, Rho and TGF- $\beta$ signalling pathway inside a maturing oocyte from cell surface receptor to transcription regulators in the nucleus. Adapted from Knobloch et al. (2007). Dotted arrows indicate indirect interactions, solid arrows indicate direct interaction. Red arrows indicate inhibition and black arrows activation of the target.

Galanti et al. (2012) studied another aspect of schistosome reproductive biology: the female developmental regression by apoptosis, when separated from the male partner. The authors described the effect of pairing and un-pairing on gene expression in female worms in vitro and compared the rate of cell proliferation and apoptosis between females from single and mixed sex infections. Apoptosis was found to be responsible for the regression of the vitellarium as part of the developmental regression that the females undergoes in response to separation from their partner (Galanti et al., 2012). Curiously, they also observed that the
rate of proliferation of the vitellarian tissue in females from SS and MS infections is very similar in vivo, but that the expansion of the vitellarium in SS females is prevented by a higher rate of apoptosis than in MS females (Galanti et al., 2012). Like the vitellarium, the ovary also undergoes growth and development once induced by stable pairing of the female with a male. Therefore it would be interesting to examine whether the transcriptome of ovaries from SS females reveals higher expression of pro-apoptotic genes compared to the ovaries from MS females. Apoptosis in Schistosoma has been previously studied by Lee et al. (2011, 2014) and Peng et al. (2010) who identified homologues of apoptosis related genes in the $S$. mansoni and S. japonicum genomes, respectively. Their results, as well as my efforts to identify other apoptosis related genes In the $S$. mansoni genome are discussed in detail in Chapter 4.2.

This work was a collaborative effort between our group and that of Prof. Dr. Christoph Grevelding. RNA was isolated from the gonads of worms from MS and SS infections as well as whole worm controls and provided to me. I used the RNA to synthesise stranded cDNA libraries for sequencing on Illumina HiSeq machines. Independent analyses of this data set (Lu et al., 2016), as well as a gene expression atlas (Lu et al., 2017) were recently published by both groups. The analysis placed greater emphasis on the evolutionary aspects of the gender interplay and examined the molecular mechanisms inducing sexual maturation. Since this experiment was conducted, our collaborators have also published a paper about the role of integrins and Venus Kinase Receptor 1 in the regulation of apoptosis in the ovaries (Gelmedin et al., 2017). The following analysis aims to define a set of ovary and testes expressed genes, as well as examining the
changes that take place in both gonads in response to pairing. To give proper context to these differentially expressed genes, I used several functional genomics approaches to show how groups of genes with similar biological functions are expressed in the gonads of $S$. mansoni and whole worms.

### 5.2 Results

### 5.2.1 Sequencing and sample clustering

In total, over 1.5 billion sequencing reads were produced, on average 63 million per sample (ranging from 42 million to 110 million), $84 \%$ of which could be mapped to the $S$. mansoni genome v5.2 (on average) (Appendix C.1).

During the initial analysis, one sample (single sex ovary 3 , sO3) was identified which had apparently been mishandled and appeared to be whole male RNA instead of an ovary sample. This became apparent on a PCA plot (Figure 5.2) and was confirmed by examining expression of known male specific transcripts (Fitzpatrick et al., 2005) (see Figure 5.3) such as those coding for the tegument allergen like (TAL) proteins (Smp_045200, Smp_086480 and Smp_195090) and calpain (Smp_137410); the sample was excluded from subsequent analysis.

Figure 5.2: Samples cluster by type, male samples from mixed sex and single sex infection cluster together. The samples are either from single sex (SS) or mixed sex (MS) infections. In this principal component analysis of RNASeq samples, $86 \%$ of the variation among all samples is explained by the two most important principal components. The PCA plot is based on the 500 most variable genes in the data set, which contains three replicates per condition. Notably one of the SS ovary samples (sO3) clustered with the whole male samples. The three Female MS samples overlap tightly.

Figure 5.3: Single sex (SS) ovary replicate 3 was more similar to SS male replicates 1-3 than other SS ovary replicates (1-2). Here the sex-biased expression of genes is used to examine an outlier. Normalised read counts of SS male and SS ovary replicates were plotted for four transcripts with known malebiased expression patterns.

The principal component analysis based on the 500 genes with the greatest variance showed that samples from tight clusters. As expected, male and female samples formed discrete clusters and, as observed in Chapter 3.2, females from MS and SS infections form separate clusters reflecting the transcriptomic (and physiological differences) between sexually mature and immature females. Again, unsurprisingly, both males from MS as well as SS infections clustered very closely, despite a small number of consistently differentially expressed genes.

Furthermore, the clusters of gonad samples resembled those of the whole worms with ovaries of MS and SS females clustering away from one another, whereas both groups of testes showed very similar transcriptomes (Figure 5.2). Generally, the organ samples clustered less tightly and showed more variation within groups than those of whole worms (Figure 5.2). This could be due to differences in RNA quality caused by the procedure used for organ extraction, although apart from lower RNA concentrations no signs of low quality were observed (Appendix C.2).

### 5.2.2 Comparing RNA-Seq to published microarray \& qPCR data

To examine how the gonad RNA-Seq data compared to similar data sets in the literature, I compared the present results to the most recent large scale effort to define the S. mansoni testes and ovary transcriptome (Nawaratna et al., 2011). In their paper, Nawaratna et al. (2011) use a powerful combination of laser microdissection and a small oligonucleotide microarray to isolate tissue from the testes and ovary of sexually mature worms from MS infections. They then compared the expression levels of " 39342 probes representing 19907 putative genes" (Nawaratna et al., 2011) in the gonads with whole worm controls, defining genes expressed 2 -fold higher in the gonads as compared with the whole worm control as "testes" and/or "ovary" genes.

To compare this data set with my RNA-Seq data the probe sequences were mapped to the $S$. mansoni reference genome v5.2 to find regions that uniquely corresponded to each probe. Splicing had to be taken into account, therefore Tophat2 was used for this process. Having determined the positions of the
probes in the genome allowed me to count RNA-Seq reads overlapping the position of these mapped probe sequences as described in the methods (Chapter 2.4.5). RNA-Seq data and microarray data are expected not to correlate linearly as RNA-Seq is expected to be more accurate at the lower and higher ends of expression (Zhao et al., 2014) as discussed in the introduction (Chapter 1.6.3). Therefore, I chose Spearman's rank correlation coefficient to measure the correlation between RNA seq and microarray expression and found there was a weak positive correlation across all samples ( $\mathrm{r}=0.46$ to $\mathrm{r}=0.54$ ), both whole worms and gonads (Figure 5.4).

In a previous analysis of the correlation between S. mansoni RNA-Seq to microarray results Protasio (2011) found that the results produced by both methods correlated well, with the correlation coefficient r ranging from 0.66 0.69. Therefore, a slightly higher correlation was anticipated in the present study, but there are several possible contributing factors to explain the lower correlation that I observed (see Figure 5.4). First, it is possible that the method of obtaining the organs, laser microdissection and protease/detergent treatment, had an impact on the transcriptome. However this is unlikely as the correlation between whole worm samples was as low as the correlation of the gonad samples. Some of the variation between samples can be explained by the use of different parasite strains; Narawatna et al. (2012) used the Puerto Rican strain of S. mansoni, whereas the strain used in our experiment on the gonad transcriptome originated in Liberia. Another reasons could be differences in the quality of the RNA used in the two experiments, but there is no way to directly compare RNA quality across the two studies.

Figure 5.4: RNA-Seq and microarray data are moderately correlated. RNASeq counts were plotted against normalised intensity values of the microarray data sets (Nawaratna et al., 2011); local regression line was plotted in red. A) Correlation of whole MS female samples. B) Correlation of ovaries from MS females. C) Correlation of whole MS males. D) Correlation of testes from MS males.

RNA-Seq counts were plotted against signal intensity of the microarray probes (see Figure 5.4). A local regression line (red) was fit onto the plots showing a weak correlation and the correlation coefficient was close to $\mathrm{r}=0.5$ for all four samples Figure 5.4). In all cases, no signal was detected for a large number of probes using one or both methods of expression analysis (Figure 5.4). Another
publication that examined gene expression in the testes and ovaries of $S$. mansoni by Hahnel et al. (2014) used qRT-PCR to measure the expression of six genes coding for the following proteins: Frizzled (Smp_173940), FGFR-A (Smp_175590), FGFR-B (Smp_157300), PMRC1 (Smp_093700), Notch (Smp_050520), Musashi (Smp_157750) using actin (Smp_161930) as a reference gene. Next, the published qRT-PCR fold changes were comparable to the fold changes measured by RNA-Seq (Appendix C.3).

The initial comparison revealed striking differences in the ratio of expression (mature ovary gene expression divided by immature ovary gene expression) (Figure 5.5).

Figure 5.5: Comparison of qRT-PCR and RNA-Seq reveals systematic differences. Expression ratio in ovaries (expression in mixed sex ovaries divided by expression in single sex ovaries) as measured by qRT-PCR and RNAseq. Generally RNA-seq ratios were all much lower suggesting less expression in paired ovaries to be lower than measured by qRT-PCR, although the trend is the same, indicating a normalisation issue.

When examining expression of the reference gene (actin) however, the RNA-Seq data suggested significant differential expression of actin between ovaries from MS and SS infections (8.1-fold higher expression in SS ovaries than in MS ovaries; adjusted p-value 6.33E-14). Eleven other published qRT-PCR reference genes (Liu et al., 2012) were examined to see whether they displayed a similar behaviour in the RNA-Seq data which would indicate of a problem with the normalisation of expression across samples. However, the other reference genes were not found to be differentially expressed and had smaller fold changes (1.3fold change on average) (Appendix C3). When taking into account the 8.1 -fold expression change of the qRT-PCR reference gene in the comparsion of gene expression between the two methods, the "adjusted" expression ratios were much closer to those reported by Hahnel et al. (2014) (Figure 5.6) and therefore provide excellent validation of the results discussed in the following sections.

Actin was not found to be expressed differentially to such large degrees in any other comparison of samples from SS versus MS infection but was still found to be significant (2.2-fold down-regulation in MS females; adjusted p value $=2.16 \mathrm{E}$ 13) in MS females (Appendix C.3).

Figure 5.6: RNA-Seq data showed good agreement with qRT-PCR after adjustment for differential expression of qRT-PCR reference gene. Expression ratio in ovaries (expression in MS ovaries divided by expression in SS ovaries) as measured by qRT-PCR and RNA-Seq as well as an adjusted RNA-Seq ratio.

### 5.2.3 Testes Transcriptome

"Testes genes" were identified using a pair-wise comparison of gene expression in testes of MS males and whole MS males using DESeq2. To be considered as "testes gene" a gene had to be differentially expressed using an adjusted p -value cut-off smaller than 0.01 and be at least 2 -fold more highly expressed in testes from MS infections than the whole male control. This threshold was used throughout this chapter to identify DEGs. 10270 out of 10828 transcipts were found to be expressed (i.e. non-zero read counts), of which 512 (5\%) were filtered out due to low expression levels using the DESeq2 independent filtering algorithm. 1949 transcripts passed the criteria to be considered "testes genes" (Figure 5.6).

Figure 5.6: The testis transcriptome differs considerably from that of whole males. A) Log ratio against mean (MA) plot of the testis-whole male comparison. Genes with an adjusted p-value of $<0.01$ are high-lighted in red; genes with a log-fold change of $>1$ (fold-change of $>2$ ) and adjusted $p$-value of $<0.01$ were called as differentially expressed "testis genes". B) PCA plot of testes of paired males and whole male control samples.

When plotting the mean expression (A) of genes against their log fold change (M) (Figure 5.6 A ), a large number of genes have large fold changes, especially those up-regulated in whole males. This is because genes expressed exclusively outside the testes should be completely absent from the testes samples, unlike the testes-specific genes, which also appear as expressed in the whole males. $99 \%$ of variation of the RNA-Seq count data between whole male and testes samples is explained by the first two principal components, most notably, the first principal component that separates the male from the testes samples explains $98 \%$ of the total variation (Figure 5.6 B). This suggests that there are large differences in
gene expression between whole male worms and testes samples and that the expression data has relatively little noise.

Amongst the most differentially expressed testes genes (adjusted p-value < 1.30E-186; Table 5.1) were DEGs coding for a cyclin dependent kinase (Smp_080730), a RNA helicase (Smp_172150), HORMA domain containing protein (Smp_169930), which is involved in DNA replication and recognition of damaged DNA (Muniyappa et al., 2014), a DNA primase subunit (Smp_079050) and a hormone receptor 4 (Smp_041540). As expected, this list suggests that the transcriptome of the testes is dominated by factors involved in mitosis. Also, a "testis expressed protein" (Smp_131630) was found to be expressed more strongly in testes than whole male. Another interesting gene found to be differentially expressed codes for the transcription factor boule (Smp_144860), which is expressed in the gonads of other Platyhelminthes, such as free-living Macrostomum lignano (Kuales et al., 2011). The transcription factor boule is also widely conserved across other animals including mammals due to its importance in the regulation of meiosis (Shah et al., 2010). I performed a whole mount in situ hybridisation to examine the specificity of boule expression in 20 male worms and detected a robust signal in the testes of all worms but no other tissues of the worm, except in the ventral sucker of four worms which are common sites of non-specific staining (see Figure 5.7).

## Boule is expressed in the testes of S. mansoni

Figure 5.7: In situ hybridisation targeting mRNA of transcription factor boule demonstrated expression in the testes of male worms. Four out of twenty worms stained for boule also exhibited staining in the ventral sucker (left). Sense transcript of boule was used as negative control (right). Even after prolonged development no distinct expression signal was noticeable in the testes. OS - Oral Sucker; VS - Ventral Sucker; T - Testes.

A GO term enrichment analysis was performed using topGO (Alexa et al., 2006) in order to get a more comprehensive picture of the function of testes genes. By testing for statistically significant (p-value $<0.01$ ) enrichment of GO terms I aimed to get a more comprehensive picture of the biological processes taking place in the testes. The testes genes were significantly enriched with DEGs from a total of 32 GO terms (Table 5.2), whereas genes up-regulated in whole males were enriched with genes from 37 GO terms (Appendix C.4). Notably, the list of
testes GO terms was dominated by mitosis related processes such as "DNA replication initiation", "spermatogenesis", "DNA repair", "cell cycle", "mitotic nuclear division" and "miss match repair", all reflecting the primary function of testes, the production of sperm. Furthermore, "microtubule-based movement" and "striated muscle contraction" were found to be up-regulated significantly in testes (Table 5.2). Spermatocytes are known to rely on microtubules for locomotion; in human sperm cells eleven microtubules are arranged into an axoneme which forms the central part of the sperm flagellum (Kierszenbaum, 2002). Furthermore, microtubules play an important role in the separation of chromosomes during meiosis and mitosis, which are expected to occur at a high rate in the testes. Striated muscle, on the other hand, has been observed to surround the testes of D. melanogaster and mammals (Kuckwa et al., 2016). "Protein glycosylation" (GO:0006486) and "protein refolding" (GO:0042026) were also significant GO terms (Table 5.2). The latter includes several genes coding for chaperone proteins such as heat shock protein 70 , which in mice plays an essential role in spermatogenesis by allowing Cdc2 and cyclin B1 to form a complex without which the developing spermatocytes become arrested at the G2-M-phase transition and undergo apoptosis (Eddy, 1999)

A KEGG pathway was performed, aimed at identifying pathways significantly enriched in testes-specific genes, including metabolic and signalling pathways among others (Chapter 2.4.10). It showed that DNA replication, mismatch repair and homologous recombination but also the Fanconi anemia (FA) pathway play an important role in the testicular tissue (Table 5.3). The FA pathway is necessary to allow the repair of damaged DNA, especially interstrand cross-links,
which are recognised by the FA core complex, which in turn activates various DNA repair proteins (Rodríguez \& D'Andrea, 2017). Additionally ribosomes, ribosome biogenesis and tRNA biosynthesis were up-regulated in testes compared to whole worms (Table 5.3). Together with mitosis-related GO terms and KEGG pathways, these biological processes such as ribosome and protein production are also indicative of rapid cell proliferation in the testes.

The mitotic activity of testes is also evident in an analysis of over-represented protein domains in the testes transcriptome; for instance, out of 75 genes coding for helicase C-terminal domains, more than half are expressed at higher levels in testes than the whole male control (only three are expressed at higher levels in the whole male control) and 27 out of 55 genes coding for DEAD/DEAH box helicase domain containing proteins are up-regulated in testes (compared with 3 in whole males) (Table 5.4). Furthermore, all 10 genes coding for minichromosome maintenance domains are up-regulated in the testes, as are all genes coding for proteins with MutS domain II, III, IV and V (all involved in DNA mismatch repair) (Table 5.4). Many of proteins with these domains play an important role in the eukaryotic DNA replication machinery as can be seen in Figure 5.8.

## Replication complex (Eukaryotes)

Figure 5.8: Most annotated S. mansoni homologues of DNA replication machinery genes are up-regulated in testes. Genes with a Schistosoma mansoni homologue are coloured in green, "testes genes" are highlighted in red. Most DNA replication genes are up-regulated in the testes transcriptome. This list highlights the important role played by many proteins with minichromosome maintenance (MCM) and helicase domains. Figure adapted from KEGG (https://www.genome.jp/dbget-bin/www_bget?hsa03030).

Notably absent from the testes genes but instead over represented in the whole male transcriptome were genes mapped to the following KEGG pathways: lysosomes, phagosome and endocytosis as well as various metabolic pathways including starch, sucrose, galactose, glucose, glycerophospholipid and amino acid metabolism (Appendix C.5), all of which are responsible for core physiology of the parasite. The whole male transcriptome was also enriched for various signalling pathways including Wnt, Fox0 and hedgehog signalling (Appendix C.5) which play important roles during development of many organisms (Eijkelenboom \& Burgering, 2013; Ingham et al., 2011; Nusse \& Varmus, 1992; Nusse \& Varmus, 2012). This is probably caused by the whole worms containing a wide variety of tissues and being more complex, including at the transctiptome level, than the testes in isolation.

| Gene ID | Description | Average <br> Read Count | Fold Change | adjusted <br> p-value |
| :--- | :--- | ---: | ---: | ---: |
| Smp_169930 | HORMA domain containing protein | 5313.73 | 34.78 | $4.14 \mathrm{E}-215$ |
| Smp_131630 | Testis expressed protein | 1452.24 | 34.07 | $1.27 \mathrm{E}-146$ |
| Smp_172150 | Putative ATP-dependent RNA | 4062.9 | 32.22 | $2.67 \mathrm{E}-223$ |
| helicase | 7395.01 | 31.12 | $2.39 \mathrm{E}-205$ |  |
| Smp_041540 | Hormone receptor 4 (dHR4) | 4169.81 | 27.19 | $2.61 \mathrm{E}-166$ |
| Smp_144860 | Boule | 3908.09 | 24.93 | $1.27 \mathrm{E}-210$ |
| Smp_079050 | DNA primase large subunit | 4902.06 | 22.78 | $1.64 \mathrm{E}-233$ |
| Smp_080730 | Cyclin dependent kinase |  |  |  |

Table 5.1: List of differentially expressed genes with testes-specific expression (see above). Average read counts are a measure of absolute gene expression; they are the average of normalised read counts across all samples. The fold changes reflect expression in the testes relative to whole male worms. The $p$-value has been adjusted for multiple hypothesis testing. See Appendix C. 6 for an expanded list.

| GO term | Description | Total Genes | DEGs | Expected | p-value |
| :---: | :---: | :---: | :---: | :---: | :---: |
| GO:0007018 | Microtubule-based movement | 60 | 36 | 9.32 | 3.40E-15 |
| GO:0006941 | Striated muscle contraction | 145 | 59 | 22.52 | 1.20E-13 |
| GO:0006270 | DNA replication initiation | 15 | 13 | 2.33 | 2.20E-09 |
| GO:0007283 | Spermatogenesis | 10 | 9 | 1.55 | 4.40E-07 |
| GO:0006281 | DNA repair | 122 | 46 | 18.95 | 7.00E-07 |
| GO:0007049 | Cell cycle | 207 | 78 | 32.15 | 2.40E-06 |
| GO:0007067 | Mitotic nuclear division | 88 | 37 | 13.67 | 3.50E-06 |
| GO:0006260 | DNA replication | 161 | 64 | 25.01 | 7.50E-05 |
| GO:0007126 | Meiotic nuclear division | 8 | 6 | 1.24 | 0.00029 |
| GO:0006298 | Mismatch repair | 11 | 7 | 1.71 | 0.0004 |
| GO:0006486 | Protein glycosylation | 58 | 15 | 9.01 | 0.00897 |
| GO:0042026 | Protein refolding | 8 | 4 | 1.24 | 0.024 |

Table 5.2: List of GO terms enriched in testes genes (see above). The column "Total Genes" provides the number of genes associated with a particular GO term. "DEGs" provides the number of genes associated with a given GO term that had significantly higher expression in testes than whole males; "Expected Genes" provides the number of differentially expressed genes associated with a given GO term that are expected by chance. The GO terms are all in the "Biological Process" category. See Appendix C. 7 for the complete list.

| Pathway | Description | Total Genes | DEGs | Expected | p-value |
| :--- | :--- | ---: | ---: | ---: | ---: |
| smm03030 | DNA replication | 30 | 24 | 7 | $5.80 \mathrm{E}-11$ |
| smm03430 | Mismatch repair | 18 | 16 | 4.2 | $5.93 \mathrm{E}-09$ |
| smm03440 | Homologous recombination | 18 | 15 | 4.2 | $1.07 \mathrm{E}-07$ |
| smm03010 | Ribosome | 110 | 47 | 25.68 | $1.88 \mathrm{E}-06$ |
| smm03460 | Fanconi anemia pathway | 27 | 17 | 6.3 | $9.39 \mathrm{E}-06$ |
| smm03008 | Ribosome biogenesis in | 62 | 22 | 14.47 | $9.86 \mathrm{E}-03$ |
| eukaryotes |  |  |  |  |  |
| smm00970 | Aminoacyl-tRNA biosynthesis | 34 | 13 | 7.94 | $2.09 \mathrm{E}-02$ |

Table 5.3: List of pathways enriched amongst the testes expressed genes (see above). The column "Total Genes" provides the number of genes in the KEGG pathway; "DEGs" provides the number of differentially expressed genes in that pathway; "Expected Genes" provides the number of differentially expressed genes in a given pathway that is expected by chance. See Appendix C. 8 for the complete list.

| Domain | Description | Total <br> Genes | DEGs | Expected | p-value |
| :--- | :--- | :---: | ---: | ---: | ---: |
| PF00271 | Helicase conserved C-terminal <br> domain | 75 | 38 | 17.68 | $2.03 \mathrm{E}-07$ |
| PF00270 | DEAD/DEAH box helicase | 55 | 27 | 12.97 | $2.19 \mathrm{E}-05$ |
| PF00493 | MCM2/3/5 family | 10 | 10 | 2.36 | $5.20 \mathrm{E}-07$ |
| PF00488 | MutS domain V | 4 | 4 | 0.94 | $3.08 \mathrm{E}-03$ |
| PF05188 | MutS domain II | 3 | 3 | 0.71 | $1.31 \mathrm{E}-02$ |
| PF05190 | MutS family domain IV | 3 | 3 | 0.71 | $1.31 \mathrm{E}-02$ |
| PF05192 | MutS domain III | 3 | 3 | 0.71 | $1.31 \mathrm{E}-02$ |

Table 5.4: List of domains enriched amongst testes expressed genes discussed above. The column "Total Genes" provides the number of genes with a given Pfam domain; "DEGs" provides the number of differentially expressed genes with that domain; "Expected" provides the number of differentially expressed genes encoding a given domain that is expected by chance. See Appendix C. 9 for an expanded list.

### 5.2.4 Ovary Transcriptome

"Ovary genes" were identified using the same method as testes genes, by doing a pair-wise comparison between ovaries of MS females and whole paired females using DESeq2. "Ovary genes" had to be differentially expressed using the same
adjusted p-value cut-off (< 0.01) and also have at least two-fold higher expression in ovaries than in the whole female control. Out of 10828 transcripts, 10213 were found to be expressed (i.e. non-zero read counts), of which 509 (5\%) were filtered out due to low levels of expression using the DESeq2 independent filtering algorithm. 1272 transcripts passed the criteria to be considered "ovary genes" (Figure 5.9A).

Figure 5.9: 1272 genes were identified as ovary-specific genes. A) Log ratio against mean (MA) plot of the ovary-whole female comparison. Genes with an adjusted p-value of $<0.01$ are high-lighted in red; genes with a log-fold change of > 1 (fold-change of $>2$ ) and adjusted p -value of $<0.01$ were called as differentially expressed "ovary genes". B) PCA plot of ovaries of paired females and whole female control samples.

Similar to the testes vs whole male comparison, the comparison of ovaries vs whole female shows a pattern, where genes up-regulated in whole females have greater fold changes than those up-regulated in ovaries (Figure 5.9B). Similarly to the testes genes, the most differentially expressed ovary genes contain genes
coding for proteins related to DNA replication and repair such as cytospin-A, as well as cell cycle controlling transcripts such as cyclins (Table 5.5) which promotes the anaphase stage of the cell cycle (Yuan \& O'Farrell, 2015). The gene boule was also found to be differentially expressed in ovaries as compared to whole worms, indicating that - like its homologue in hermaphroditic flatworms it is expressed in both testes and ovaries (Kuales et al., 2011). A "testis expressed protein" gene (Smp_131630) was found to be up-regulated in the ovaries as well (Table 5.5). In mice it contributes to the formation of intercellular bridges, making it essential for spermatogenesis. It plays the same role in the development of oocytes, although knock-outs of testis expressed gene 14 does not lead to sterility in females (Greenbaum et al., 2009).

The results of the GO term analysis of ovary genes (Table 5.6) were very similar to that of the testes genes (Table 5.2). The ovary genes are enriched for 36 GO terms, 20 of which are shared with the GO terms enriched in the testes genes and include: "DNA replication initiation" and "DNA repair", "mitotic nuclear division", "miss-match repair" and "protein glycosylation". Other GO terms enriched in the testes and ovary genes include cell cycle control and regulation of cell proliferation: "cell proliferation", "negative regulation of cell proliferation", "cell cycle" and "meiotic nuclear division". Unlike testes genes, which are not overrepresented in GO terms for signalling, the ovary genes are over-represented in "regulation of Rho protein signal transduction". Almost four times more ovary genes associated with that GP-term are up-regulated significantly when compared to the expected number of such genes ( 23 up-regulated, 6 expected). The results above are summarised in Table 5.6.

The KEGG pathway analysis also highlighted the importance of DNA replication, the FA pathway and mismatch repair pathway, which were significantly upregulated in the ovary transcriptome (Table 5.7). Additionally the analysis indicated a high rate of protein synthesis in this tissue, with ovary genes being over represented in Ribosome, Ribosome Biogenesis and other related pathways (Table 5.7).

Even more so than in the testes genes, the ovary genes were significantly enriched with genes coding for helicase (both C-terminal helicase domains and DEAD/DEAH box helicase domains) and MCM domains (both the N-terminal domain and the MCM2/3/5 family domain). These were the three most significantly enriched domains, with between $77-100 \%$ (compared to $30 \%$ expected by chance) of genes coding for such domains being expressed at significantly higher levels in ovaries compared to whole females (Table 5.8). Another significant domain was the BRCA1 $C$ Terminus domain (BRCT), belonging to a group of genes involved in DNA repair and is most known for its role in breast cancer (Friedenson, 2007). All nine S. mansoni genes coding for this domain had at least 2 -fold higher expression in the ovaries than whole females (Table 5.8).

Genes with noticeably low expression in the ovaries included those involved in digestion and metabolism of nutrients (in particular KEGG pathways such as lysosome, phagosome and endocytosis as well as amino acid and sugar metabolism) (Appendix C.10. Other pathways which were also expressed at low
levels in ovaries were signalling pathways such as Fox0 (smm04068), hedgehog (smm04340) and neuroactive ligand-receptor interactions (smm04080). These results were found to be similar to those of the testes transcriptome, reflecting the function of germ cell production common to both gonad tissues.

| Gene ID | Product | Average Read <br> Count | Fold Change | adjusted <br> p-value |
| :--- | :--- | ---: | ---: | ---: |
| Smp_144860 | Boule | 1998.21 | 16.06 | $1.34 \mathrm{E}-147$ |

Table 5.7: KEGG pathways enriched amongst the genes up-regulated in the ovaries of paired females (see above). The column "Total Genes" provides the number of genes in the KEGG pathway; "DEGs" provides the number differentially expressed genes in that pathway; "Expected Genes" provides the number of differentially expressed genes in a given pathway that is expected by chance. See Appendix C. 13 for the complete list.

| Domain | Description | Total <br> Genes | DEGs | Expected | p-value |
| :--- | :--- | ---: | ---: | ---: | ---: |
| PF00271 | Helicase conserved C-terminal domain | 75 | 58 | 22.29 | $1.360 \mathrm{E}-17$ |
| PF00270 | DEAD/DEAH box helicase | 55 | 43 | 16.35 | $1.126 \mathrm{E}-13$ |
| PF00493 | MCM2/3/5 family | 10 | 10 | 2.97 | $5.309 \mathrm{E}-06$ |
| PF00533 | BRCA1 C Terminus (BRCT) domain | 9 | 9 | 2.68 | $1.791 \mathrm{E}-05$ |
| PF14551 | MCM N-terminal domain | 6 | 6 | 1.78 | $6.865 \mathrm{E}-04$ |

Table 5.8: Pfam domains enriched amongst the genes up-regulated in the ovaries of paired females (see above). The column "Total Genes" provides the number of genes encoding the Pfam domain; "DEGs" provides the number of differentially expressed genes coding for the domain; "Expected" provides the number of differentially expressed genes coding for the domain that is expected by chance. See Appendix C. 14 for an expanded list.

### 5.2.5 Comparing the Testes and Ovary Transcriptomes

To identify genes that serve common function in the testes and ovary of $S$. mansoni, I examined the intersection between the sets of "testes genes" and "ovary genes". Out of 1949 testes genes and 1272 ovary genes, 715 were shared (Figure 5.10). The 715 DEGs were over-represented in many mentioned GO terms discussed in Chapters 5.2.3 and 5.2.4. This includes DNA repair and
replication, both mitotic and meiotic nuclear division, striated muscle contraction and microtubule based movement (Figure 5.10). However, there are interesting differences when looking at the genes expressed in ovaries and testes. While "testes genes" showed an expected enrichment for spermatogenesis, the "ovary genes" included an enrichment for genes of the Notch signalling pathway (Figure 5.10) which is known to be interconnected with Rho signalling and is a highly conserved pathway found in all metazoans (Boureux et al., 2007; Schwartz, 2004). The Notch signalling pathway (GO:0007219) was represented by 22 genes ( 4 expected, $\mathrm{p}=0.033$ ) (Appendices C.15-16).

Fewer genes had ovary-specific expression compared to the testes (Figure 5.10). In the differential expression analysis, ovary-expressed genes were found to have a lower median fold-change than testes genes (6.51 and 14.03-fold change respectively). As a result, more testes genes had a fold-change above the significance threshold (fold change > 2).

Testes
Ovaries

Figure 5.10: More testes-specific than ovary-specific genes were identified with distinct functions in the two groups of genes. The numbers indicate the testes and ovary "specific" genes as well as genes shared by both. A selection of significantly enriched GO terms is given for each category. The 715 shared genes were found to be strongly enriched for DNA replication related functions. This included repair and chromosome maintenance. The genes expressed in testes contained many spermatogenesis-specific genes whereas the genes expressed in ovaries included genes that regulate multicellular organismal development and Notch signalling pathway genes.

### 5.2.6 Effect of pairing on testes transcriptome

The effect of pairing on the testes transcriptome is, like the effect of pairing on the male overall, relatively small. The aim was to identify pairing-related transcriptome changes in the testes. By excluding all non-testes specific transcripts, small transcriptome changes in the testes should be more easily detected, allowing more differentially expressed testes-specific genes to be identified. Genes differentially expressed between testes of males from MS and SS infections were identified by doing a pair-wise comparison using DESeq2.

Figure 5.11 Few differentially expressed genes $s$ were identified in comparison of testes from single sex (SS) and mixed sex (MS) infections. A) Log ratio vs mean (MA) plot of the SS testes - MS testes comparison. Genes with an adjusted p-value of < 0.01 are high-lighted in red; triangles indicate genes outside the boundaries of the plots; like other genes, they are red if they are statistically significant, grey if they are not. Genes with a log-fold change of >1 (fold-change of $>2$ ) and adjusted p-value of $<0.01$ were called as differentially expressed "testes genes". B) PCA plot of testes of MS males and testes of SS males. $81 \%$ of variation across samples is explained by the two components.

10348 out of 10828 transcripts were found to be expressed (i.e. non-zero read counts), of which 2555 ( $25 \%$ ) were filtered out due to low levels of expression using the DESeq2 independent filtering algorithm (Figure 5.11). 17 transcripts were found to be significantly up-regulated in testes of MS worms (Table 5.9), whereas only 3 were found to be down-regulated (Table 5.10). None of these genes had been found to be differentially expressed in the comparison of whole males from MS and SS infections.

| Gene ID | Description | Average <br> read count | Fold <br> change | Adjusted <br> p-value |
| :--- | :--- | ---: | ---: | ---: |
| Smp_179370 | Putative low-density lipoprotein <br> receptor | 298.44 | 3.94 | $9.67 \mathrm{E}-13$ |

| Smp_004530 | Uncharacterised protein | 68.27 | 2.14 | $2.09 \mathrm{E}-03$ |
| Smp_014570 | Saposin-like protein | 104.84 | 2.10 | $2.09 \mathrm{E}-03$ |
| Smp_139530 | Tumour protein p63 | 89.43 | 2.08 | $2.40 \mathrm{E}-03$ |
| Smp_053520 | Homeobox protein aristaless-like | 61.39 | 2.03 | $5.27 \mathrm{E}-03$ |

Table 5.9: Differentially expressed genes up-regulated in testes of males from mixed sex infections. Average read counts provide a measure of absolute expression for a given gene. The fold changes reflect expression in testes of males from mixed sex infections compared to testes of males from single sex infections. The $p$-value has been adjusted for multiple hypothesis testing.

| Gene ID | Description | Average <br> read count | Fold <br> change | Adjusted <br> p-value |
| :--- | :--- | ---: | ---: | ---: |
| Smp_166530 | Phospholipase A | 431.09 | 2.23 | $4.45 \mathrm{E}-05$ |
| Smp_130280 | Uncharacterised protein | 59.57 | 2.08 | $2.72 \mathrm{E}-03$ |
| Smp_018170 | Krupple-like zinc finger protein | 42.67 | 2.04 | $4.12 \mathrm{E}-03$ |

Table 5.10: Genes up-regulated in testes of males from single sex infections. Average read counts provide a measure of absolute expression for a given gene. The fold changes reflect expression in testes of males from single sex infections compared to testes of males from mixed sex infections. The $p$-value has been adjusted for multiple hypothesis testing.

For this comparison the number of differentially expressed genes was so low that no reliable results could be obtained from the enrichment analysis. All three types of analysis, GO term, KEGG pathway and Pfam domain enrichment, returned statistically significant results for both MS and SS testes, but often these were based on as few as a single gene so that the results where not convincing from a biological point of view.

## Follistatin - SmFst

Leutner et al. (2013) suggested in their paper on pairing experienced, i.e. MS, and inexperienced, i.e. SS, males that follistatin or SmFst (Smp_123300) might play a regulatory role in the testes of adult S. mansoni. This was based on the observation that SmFst was consistently up-regulated in SS males when compared to MS males (an effect that was replicated in this data set also (2.3x expression in SS males compared to MS males; adjusted p-vale $=1.50 \mathrm{E}-08$ ), as well as an in situ hybridisation experiment suggesting a testes-specific pattern of SmFst expression (Leutner et al., 2013). However, the testes-specific nature of SmFst expression could not be detected using RNA-Seq, instead our data suggested an almost 10 -fold higher expression of SmFst outside the testes
(adjusted p-value $=4.29 \mathrm{E}-11$ ) (Appendix C.17). Furthermore, our data revealed that SmFst expression is not limited to male worms but is similarly downregulated in MS females (12-fold decrease in MS females; adjusted p-value $=$ $9.46 \mathrm{E}-31$ ) and ovaries of MS and SS females (9-fold decrease in ovaries from MS worms; adjusted p-value = 8.58E-12) (Appendix C.18).

### 5.2.7 Effect of pairing on ovary transcriptome

Unlike the small transcriptome changes found in the testes, in ovaries the changes induced by pairing are of a much greater magnitude. Out of 10828 examined genes, 10217 had non-zero read counts of which 1019 genes were filtered out due to low read counts using the DESeq2 independent filtering algorithm (Figure 5.12).

Figure 5.12 Over 2700 DEGs were identified in comparison of ovaries from single sex (SS) and mixed sex (MS) infections. A) Log ratio against mean (MA) plot of the SS ovaries - MS ovaries comparison. Genes with an adjusted p-value of < 0.01 are highlighted in red; triangles indicate genes outside the boundaries of the plots; like other genes, they are red if they are statistically significant, grey if they are not. Genes with a log-fold change of $>1$ (fold-change of $>2$ ) and adjusted p-value of $<0.01$ were called as differentially expressed "ovary genes". B) PCA plot of ovaries of MS and SS females. 93\% of variation across samples is explained by the experimental conditions in this PCA.

Of the remaining genes, 2769 were found to be differentially expressed in response to pairing ( 966 up-regulated in MS ovaries and 1803 up in ovaries of SS females) (Figure 5.12A). Many of the genes differentially expressed between the ovaries of MS and SS females had not been identified as "ovary genes" in Chapter 5.2.4. Instead they were expressed in the rest of the female worm as well. Out of the 2769 DEGs in this comparison, 574 were "ovary genes". It shows that pairing dependant regulation of gene expression is not limited to "ovary genes" but also affects many genes expressed throughout the body of female worm. Particular
the vitellarian tissue undergoes significant growth and cell proliferation though at an even larger scale than the ovaries.

Initially, I examined the genes up-regulated in MS ovaries (summaries in Table 5.11). The list of GO term these genes were enriched with was dominated by all aspects of translation, but also included "cell-matrix adhesion", "integrinmediated signalling pathway" and "neurotransmitter transport" (Table 5.12 and Appendix C.19). Female maturation is linked to a neural signal, neuropeptide-Y 8 (Collins \& Newmark, 2013) and cell proliferation of oogonia is thought to be stimulated by integrin signalling among others (Beckmann et al., 2012).

Genes up-regulated in MS ovaries coded for proteins that for part of the KEGG pathways responsible for gene expression and protein production: "RNA transport", "RNA polymerase" and "pyrimidine metabolism" indicated a high rate of transcription whereas "ribosome", "ribosome biogenesis" and functionally related pathways such as "aminoacyl-tRNA biosynthesis" represented the translational activity of the mature ovaries, all of which is fuelled by a more highly transcribed "oxidative phosphorylation" pathway (Table 5.13).

When examining enriched protein domains, these same processes were found to be enriched (Table 5.14). Amongst genes up-regulated in MS ovaries were many coding for proteins with domains such as helicase domains and RNA polymerase Rpb2 domains as well as RNA recognition motifs, 50S ribosome-binding GTPase domains, tRNA synthetase class I domains and different ribosomal protein domains (Table 5.14). Additionally, mitochondrial specific domains were
significantly enriched, including ATP synthase subunit C and mitochondrial carrier protein (Table 5.14). Highlighting the mitogenic activity within the mature ovaries, genes cofing for proteins with cyclin domains were differentially expressed at higher levels than expected by chance in the MS ovaries. Cyclins play a key role in regulating the cell cycle by controlling the progression from one stage to the next (Sclafani \& Holzen, 2007). Comparing the expression levels of all genes annotated as cyclin, cyclin dependant kinases (CDK), or cell division cycle protein (CDC), there were a total of 38 genes that formed two distinct clusters based on their expression (Figure 5.13). This provided further evidence for differential regulation of the cell cycle in MS and SS ovaries.

Figure 5.13: Many genes involved in cell cycle regulation, including cyclin, CDK and CDC genes are up-regulated in mix sex ovary samples. Three RNAseq replicates of mixed sex (MS) ovary (MS ovary 1-3) and two replicates of single sex (SS) ovary (SS ovary 1-2) were used to generate this figure. Colours represent a Z-score of log transformed normalised read counts scaled by row, providing relative measures of gene expression in each sample (measured in standard deviations from the mean). Average normalised read counts for each gene are in the row on the right on a logarithmic scale as a measure of absolute expression levels. See Appendix C. 20 for a description of these cell cycle genes.

The MAPK, Rho and TGF- $\beta$ signalling pathways have been examined closely and are known to play an important role in the development of the female sexual maturity (Andrade et al., 2014; Osman et al., 2006; Santos et al., 2002). To examine the processes that lead to the initiation of the MAPK pathway in the cells of the ovaries and induce maturation of the tissue I compiled a list of the well established $S$. mansoni genes involved in the signalling network that transmits the male stimulus to the nuclei of ovary cells (Andrade et al., 2014; Beckmann et al., 2010; Knobloch et al., 2007; Oliveira et al., 2012; Osman et al., 2006) and created a heat map of normalised read counts for the ovary samples (Figure 5.14). This set of genes was also clustered into two expression groups, one up-regulated in the ovaries of MS females and one down-regulated when compared to ovaries of female worms from SS infections (Figure 5.14). The signalling network features over 40 members with different regulatory function that, in response to pairing, drive the cell cycle towards DNA replication and the reorganisation of the cytoskeleton to allow for cell division (Beckmann et al., 2010).

Figure 5.14: Many genes of the MAPK, Rho and TGF- $\beta$ signalling pathways are differentially expressed in the mixed sex (MS) and sngle sex (SS) ovary samples. Three RNA-seq replicates of MS ovary (MS ovary 1-3) and two replicates of SS ovary (SS ovary 1-2) were used to generate this figure. Colours represent a Z-score of log transformed normalised read counts scaled by row, giving relative measures of gene expression in each sample. Average normalised read counts for each gene are in the row on the right on a logarithmic scale as a measure of absolute expression levels. See Appendix C. 21 for a description of these MAPK signalling genes.

Unlike in Figure 5.13, where the expression of genes coding for cyclins, CDCs and CDKs was compared, the picture emerging from a comparison of genes coding for proteins involved in MAPK, TGFb and integrin signalling was less clear. Although a large number of these genes were up-regulated in the MS ovaries, a similar number of genes had greater expression in the ovaries of SS females (Figure 5.14). Up-regulation of genes in the SS ovaries was by no means limited to genes coding for proteins with inhibitory functions but included genes coding for some of the key regulators of the MAPK signalling pathway such as homologues of Rho, Ras-guanine nucleotide exchange factor, Raf and Erk (Figure 5.15). Others, such as genes coding for growth factor receptor-bound protein 2 and Ras, showed no differentially expression (Figure 5.15). In contrast, the genes coding for SMAD2 and 4 as well as Transforming Growth Factor- $\beta$ Receptor II, Ras-GAP and Scr-cytoplasmic tyrosine kinase homologues were found to be upregulated in MS ovaries (Figure 5.15). Ultimately however, the induction of cell proliferation is dependent on receiving specific extracellular stimuli provided by pairing as well as host factors to initiate signalling and mitogenic activity and cell differentiation (Beckmann et al., 2010).

Figure 5.15: Many members of the MAPK, Rho and TGF- $\beta$ signalling pathway are differentially expressed in ovaries. Adapted from Knobloch et al. (2007). Dotted arrows indicate indirect interactions, solid arrows indicate direct interaction. Red arrows indicate inhibition and black arrows activation of the target. Red coloured genes are up-regulated in the ovaries of MS females, blue coloured genes are up-regulated in the ovaries of SS females, grey coloured genes are not differentially expressed.

| Gene ID | Description | Average <br> Read Count | Fold <br> change | Adjusted <br> p-value |
| :--- | :--- | ---: | ---: | ---: |

Table 5.11: Most differentially expressed genes up-regulated in the ovaries of females from mixed sex infections compared to ovaries from single sex infections. Average read counts provide a measure of absolute expression for a given gene. The fold changes reflect expression in ovaries of females from mixed sex infections compared to ovaries of females from single sex infections. The $p$ value has been adjusted for multiple hypothesis testing. Some p-values were calculated to be equal to 0 , highlighting how statistically significant the differential expression of these genes was.

| GO term | Description | Total <br> Genes | DEGs | Expected | p-value |
| :--- | :--- | ---: | ---: | ---: | ---: |

Table 5.14 Pfam domains enriched amongst the genes up-regulated in ovaries the of females from mixed sex infections compared to ovaries from single sex infections (see above). The column "Total Genes" provides the number of genes with a given Pfam domain. "DEGs" provides the number of differentially expressed genes with that domain; "Expected" provides the number of DEGs with a given domain that is expected by chance. See Appendix C. 23 for an expanded list.

Next, I examined the genes upregulated in SS ovaries, the most differentially expressed of which are summarised in Table 5.15. Genes up-regulated in the ovaries of SS females were enriched for a total of 38 GO terms (Table 5.16). Interestingly these GO terms included "spermatogenesis" and "male sex determination" (Table 5.16), two biological processes that intuitively are associated with testes rather than ovaries. In the case of the "male sex determination" the genes in question included negative regulators of transcription (Logan-Klumpler et al., 2012) via the MAPK signalling pathway such as a capicua (Smp_142600) and a SOX family transcription factor homologue (Smp_148110) (Hargrave et al., 2000; Jimenez et al., 2012) as well as
two members of the Wnt signalling pathway (Logan-Klumpler et al., 2012) responsible for regulating embryogenesis in D. melanogaster, a pangolin (Smp_131260) and transcription factor 7 -like-2 (Smp_148190) homologue (Jin \& Liu, 2008; Ravindranath \& Cadigan, 2014) which also play a role in the ovaries. The "spermatogenesis" genes include three homologues of the gene coding for the "spermatogenesis associated proteins" (Logan-Klumpler et al., 2012) but their function is not necessarily involved exclusively in spermatogenesis; they fulfil varied roles, such as apoptosis regulation and degradation of mitochondrial proteins (Jiang et al., Wang, 2013; Puri et al., 2011). Additionally, two nanos homologues (Smp_051920, Smp_055740) are included (Logan-Klumpler et al., 2012), which play an important role in spermatogenesis but were also shown to be involved in oocyte development by maintaining the adult germlines in $D$. melanogaster (Bhat, 1999). Furthermore the "spermatogenesis" GO term included two lin54 protein homolouges (Smp_022870, Smp_178740) (LoganKlumpler et al., 2012), which are both involved in the regulation of the cell cycle. They are components fo the DREAM complex, which regulates gene expression at various points throughout the cell cycle (Schmit et al., 2009). Other interesting GO terms included the "Wnt signalling pathway", "cell cycle arrest", and "cell differentiation" (Table 5.16). These GO terms were further evidence for the strict control of cell proliferation in the ovaries of SS females. Finally a significant proportion of genes annotated with the GO terms "Fatty acid biosynthetic process" and "Sphingolipid metabolism" were up-regulated (Table 5.16).

Next, a pathway analysis was performed using the KEGG reference pathways for S. mansoni. The aim was to identify any pathways containing more up-regulated
genes than expected by chance. The pathway analysis of the SS ovary genes revealed 14 pathways to be significantly up-regulated (Table 5.17). Metabolic pathways, including amino acid metabolism, carbohydrate metabolism and lipid metabolism notably including "sphingolipid metabolism" were found to be enriched with DEGs (Table 5.17). Several developmental signalling pathways were also found to be over-represented among the DEGs, such as Wnt signalling and dorsal-ventral axis formation, similar to the GO terms found up-regulated in the SS ovaries (Table 5.17). The SS ovary genes were also examined for Pfam domain enrichment with 77 different domains found to be enriched (Table 5.18). Among them were genes coding for domains that control apoptosis, such as the Bcl-2 domain and growth factor domains, such as Calcium-binding EGF domains, complement clr-like EGF-like domains and growth factor receptor domain IV (Table 5.18).

Since Galanti et al. (2012) observed apoptosis to be occurring at a higher rate in the vitellarian tissue of SS females compared to MS females, I examined whether similar activity could be detected in the ovary transcriptome. I first noted that all four genes known to code for Bcl-2 domains were up-regulated in ovaries of SS females (Table 5.18). Furthermore, ceramide, one of the central metabolites of the sphingolipid metabolism pathway that was significantly up-regulated in the ovaries of SS females (Table 5.17), is also an important regulator of apoptosis (Bose et al., 1995; Jensen et al., 2014; Separovic et al., 2012). Bose et al. (1995) showed that ceramide synthase mediates an alternative pathway of apoptosis activation. Sparovic et al. (2012) showed that human cells became more resistant to apoptosis when ceramide synthase was knocked down using RNAi.

Finally, Jensen et al. (2014) discovered that a member of the Bcl-2 family, a group of apoptosis regulating protein, can inhibit ceramide synthase. The mitochondira associated protein Bcl-2-like 13 blocks apoptosis by inhibiting ceramide synthase, thereby linking sphingolipid metabolism and the Bcl-2 regulated apoptosis machinery (Jensen et al., 2014). In the ovaries of SS females, a homologue of ceramide synthase (Smp_042440) was 2.5 -fold up-regulated (adjusted p value $=1.74 \mathrm{E}-07$ ) (Table 5.15) and as can bee seen in Figure 5.16, several other genes involved in the biosynthesis of ceramide were up-regulated as well.

Figure 5.16: Many genes involved in sphingolipid metabolism are differentially expressed in ovaries from single sex (SS) and mixed sex (MS) infections. The genes encoding red coloured enzymes are up-regulated in ovaries of SS females, genes coding for blue coloured enzymes are downregulated in the ovaries of SS females. Arrows indicate the catalysed reaction. Adapted from KEGG reference pathway. URL: http://www.kegg.jp/keggbin/highlight_pathway?scale=1.0\&map
=smm00600\&keyword=sphingolipid.

I used the list of 28 putative apoptosis-related genes from Chapter 4.2.2 to examine the apoptosis in the ovaires. These genes had been identified using a combination of previously published literature (Lee et al., 2011, Lee et al., 2014; Peng et al., 2010) as well as Interpro Scan, Pfam and BLAST comparison (see Chapter 2.4.12 for method; see Appendix B2-10 for more details). Several groups of genes, such as cytochrome C genes ( 21 genes in total), known to be involved in apoptosis were excluded from this heat map due to the size of these gene families and due to their role in many other cellular processes. In total, six out of 13 putative pro-apoptotic factors were significantly up-regulated in the ovaries of SS females, whereas only one was significantly up-regulated in the ovaries of MS females (six not significantly differentially expressed) (Appendix C.24). In contrast, six out of nine putative anti-apoptotic genes were significantly upregulated in the ovaries of MS females and only one in the ovaries of SS females (two were not significantly differentially expressed) (Appendix C.24). Of the six genes for which it was unknown whether they are pro- or anti-apoptotic two Smp_168470 \& Smp_148130 - were significantly up-regulated in the ovaries of SS females and four - Smp_043360, Smp_022110, Smp_084610 \& Smp_196040 were up-regulated in the ovaries of MS females. If the assumption that proapoptotic genes are up-regulated in SS ovaires and anti-apoptotic genes are down-regulated is correct, Smp_043360 (sBH3), Smp_022110 (p21 activated protein kinase interacting protein), Smp_084610 (FAS associated factor 2) and Smp_196040 (SHC transforming protein 3) may have anti-apoptotic activity, whereas Smp_168470 (Bcl-2 family protein) and Smp_148130 (FAS binding factor) could have pro-apoptotic functions (see Figure 5.17). However to confirm
or dismiss these predictions careful characterisation of these genes using RNAi or other methods should to be performed.

Figure 5.17 Expression of apoptosis-related genes points to higher levels of apoptosis in the ovaries of females from single sex (SS) infections than those of females form mixed sex (MS) infections. Three RNA-seq samples of MS ovary (MS ovary 1-3) and two SS ovary (SS ovary 1-2) were used to generate this figure. Colours represent a Z-score of log transformed normalised read counts scaled by row, giving relative measures of gene expression in each sample. Average normalised read counts for each gene are in the row on the right on a logarithmic scale as a measure of absolute expression levels. Samples were clustered by similarity of expression patterns, forming the expected groups of single sex and mixed sex ovaries. Genes were also clustered by expression. Genes were either categorised as pro-apoptotic (+), anti-apoptotic ( - ) or with unknown regulatory function (?).See Appendix C. 24 for a description of these putative apoptosis-related genes and their expression in ovaries.

| Gene ID | Description | Average <br> Read Count | Fold <br> change | Adjusted <br> p-value |

Table 5.18 Pfam domains enriched amongst the in genes up-regulated in ovaries of females from single sex infections compared to ovaries from mixed sex infections (see above). The column "Total Genes" provides the number of genes encoding a given Pfam domain. "DEGs" provides the number of differentially expressed genes with that domain; "Expected" provides the number of dfferentially expressed genes encoding a given domain that is expected by chance. See Appendix C. 27 for an expanded list.

### 5.3 Discussion

When examining the published results (Hahnel et al., 2014) on differential expression in mature (MS) and immature (SS) gonads, differences emerged both in terms of direction and magnitude of the observed changes. These discrepancies could be resolved by taking into account changes in the expression of the reference gene, actin, which was shown to be distinctly differentially expressed across mature and immature ovaries. After applying this calibration, both sets of data agreed well, not only in terms of the direction of differential expression but also the magnitude of the changes measured, strengthening the confidence that can be placed in this data set as well as highlighting the importance of choosing appropriate internal reference genes for qPCR analysis. There are several papers discussing the role of pairing-induced signalling through various pathways on actin and its role in the remodelling of the cell cytoskeleton (Beckmann et al., 2010; Faix \& Grosse, 2006; Knobloch et al., 2007; Olson, 2003; Wallar \& Alberts, 2003). As a result, differential expression of actin between ovaries of SS and those of MS females is not entirely unexpected, although the magnitude of the change was surprising. This analysis suggests that actin should be used very carefully as a reference gene for qRT-PCR. Instead a more rational choice of internal reference gene, such PSMD4, another gene recommended by Liu et al. (2012), may more suitable, especially when comparing samples from different life cycle stages, different genders or different pairing statuses.

Comparing the number genes identified to be gonad specific by Nawaratna et al. (2011) to this analysis several differences become apparent. Nawaratna et al. (2011) identified 2141 probes, corresponding to 1188 genes, to be testesspecific and 4352 probes, 1989 genes, to be ovary-specific. In the present study, 1949 testes-specific and 1272 ovary-specific genes were found, despite using the same threshold for gonad specificity (a two-fold higher expression in the gonads compared to the whole worm control). In this context it is interesting to note that Nawaratna et al. (2011) had two biological replicates for testes, but only one sample for ovaries (and only single sample for both male and female whole worm controls). This may explain some of the discrepancy between the microarray and RNA-Seq results.

The transcriptome analysis of ovaries and testes reflected their known biological functions closely with both highly enriched for genes involved in DNA replication and cell proliferation/division genes as suggested by GO term, KEGG pathway and Pfam domain enrichment analysis. The domain enrichment analysis highlighted a significant enrichment of genes involved in faithful DNA replication compared to the whole worm transcriptome, showing all genes with MutS and BRCA domains being expressed at higher levels in the gonads than the whole worm controls. These findings do not come as a great surprise, given that germ cell maintenance as well as spermatocyte and oocyte production are the main function of the testes and ovaries respectively. Similar to Nawaratna et al. (2011), this analysis showed cyclins, CDCs and CDKs to be expressed at higher levels in the gonads than in the somatic tissues of the adult worms.

Few changes in gene expression were found in the testes in response to pairing. This is in good agreement with the literature that suggests little change except a small shrinkage of testes, which was observed in MS male worms. Follistatin, which was hypothesised by Leutner et al. (2013) to be testes specific, was not found to be expressed at higher levels in the testes than whole males nor was it found to be differentially expressed in the testes of MS and SS males. Nonetheless a down-regulation of follistatin in MS males was observed in this experiment, as had been previously reported by Leutner et al. (2013). This suggests that SmFst plays a role in the response of male worms to pairing that is unrelated to the testes. Rather its function appears to take place in the somatic tissues of male worms, which was unexpected.

The small transcriptome changes in testes stood in stark contrast to those in the ovaries. In the ovaries of MS females, clear up-regulation of cell cycle regulating genes was seen, including cyclins, CDCs and CDKs, which play a pivotal in the tight control of DNA replication and repair in eukaryotes (Sclafani \& Holzen, 2007) to allow for successful mitosis and meiosis. The higher expression of those genes in MS females emphasised the higher rate of cell division and proliferation in females worms from MS infections compared to female worms from SS infections, as expected from our current knowledge of the effect of pairing on the ovaries.

In addition to the cell cycle regulating proteins, many genes involved in Rho and MAPK signalling pathway - known to regulate proliferation and maturation of
ovaries in response to pairing (Beckmann et al., 2010) - were differentially regulated between SS and MS ovaries. Although no clear pattern of up- or downregulation of this group of genes emerged, the large, statistically significant proportion of these genes expressed differentially between immature and mature ovaries, reinforces the key role that the MAPK pathway plays in regulating ovary growth. As discussed in the introduction, Rho is thought to be an important member of the group of genes regulating cell proliferation in the ovaries in response to pairing (Beckmann et al., 2010). Rho signalling allows cells to respond to a variety of extracellular signals, including growth factors, cytokines and hormones (Schwartz, 2004). This could be part of the mechanism that regulates the pairing-induced fertility in female worms.

The changes that took place in the ovary transcriptome in response to pairing were also highly suggestive of apoptosis playing an important role in controlling ovary maturation before pairing. Two important aspects of this process are the sphingolipid metabolism (Tirodkar \& Voelkel-Johnson, 2012) and secondly a set of proteins including Bcl-2 domain containing proteins, caspases, BAX domain containing proteins and apoptosis inhibitors (Lee et al., 2011). The sphingolipid metabolism pathway was significantly up-regulated in SS females, with ceramide synthase, a known positive regulator of apoptosis in human cells (Separovic et al., 2012), being 2.5 -fold more expressed in SS ovaries than MS ones. On the other hand, neutral ceramidase, known to have a protective effect on cells in rat cells (Zhu et al., 2008), was also up-regulated, suggesting that proliferation and apoptosis were carefully balanced in SS ovaries.

Further evidence of the important role apoptosis plays in the regulation of ovary proliferation before pairing was based on classification of apoptosis genes in schistosomes by Lee et al. (2014) as well as BLAST and Pfam evidence. Many putative pro-apoptotic genes were found to be expressed in the ovaries of SS females in contrast to the high level of expression of putative anti-apoptotic genes in the ovaries of MS females. These findings were consistent with the high levels of apoptosis reported in vitellarian tissue of SS females by Galanti et al. (2012) and point to a common regulatory mechanism for the proliferation of both these tissues, which are intimately involved in egg production.

Chapter 6

Concluding remarks

Sexual maturation of female schistosomes is critically dependant on stimulation by a male partner, as is well established (Basch, 1991). In the absence of a male stimulus, the female worms remain developmentally stunted without mature ovaries and vitellaria on which egg production depends. While the differences between fully mature females and immature females had already been explored extensively [for example Fitzpatrick \& Hoffmann (2006) and Waisberg et al. (2007)] when I started working on this thesis, a time course of gene expression, measured using RNA-Seq, over the course of female development was not available. This time course revealed the changes in gene expression as they occurred over time after pairing commenced, rather than just the gene expression of fully mature females. Many studies have examined the signalling cascade that leads to the proliferation of cells in the female reproductive organs (see Chapter 1.5) and there was already evidence for the involvement of neuropeptides (Collins et al., 2010) as well as apoptosis (Galanti et al., 2012) playing an important role in female development, and particularly regulating cell proliferation in female reproductive organs.

Recently, several papers examined the changes in genes expression over the course of schistosome maturation (Cai et al., 2016; Wang et al., 2017). One of their aims was to discover the precise stimulus used by male worms to induce maturation in females. The nature of this stimulus has been the subject to research and speculation of years, but has remained elusive (Chapter 1.4). Wang et al. (2017) used their expression data to identify genes whose expression was correlated with paring or vitelline development. Wang et al. (2017) hypothesised that an aromatic-L-amino acid decarboxylase (AADC) gene, which they showed
to be expressed in the gynecophoral canal of male worms using WISH, was responsible for the stimulation of female worms. The authors did not present RNAi evidence showing that knock down of AADC prevented female maturation as they did for another gene in the same paper. Thus, the evidence for AADC inducing female fertility seems somewhat circumstantial at this point, as it appears to be based on a correlation of AADC expression with female fertility, as well as the expression in the gynecophoral canal. Furthermore, data from Chapter 3 showed that the S. mansoni homologue of AADC is expressed in a paring-dependant manner. However, that would raise the question of how male worms are stimulated to express AADC. More concrete evidence, such as RNAi experiments, similar to that provided for the allatostatin receptor in the same publication (Wang et al., 2017), would greatly strengthen this hypothesis.

This thesis examined the events leading to maturation of female worms starting with pairing and the male-female interaction. This is an important aspect of schistosome biology for many reasons. In particular, if untreated, adult schistosomes survive for years inside the mammalian host, and their egg production is responsible for much of the pathology associated with schistosomiasis as well as its transmission. Hopefully the information gathered here can help to identify new avenues in the search for novel drug targets and therapies. Praziquantel, the current drug of choice for the treatment of schistosomasis, is not effective against developing parasites and also faces the challenge of emerging resistance (Crellen et al., 2016).

## Divergent development of males and females

In Chapter 3, the development of male and female worms was examined at the transcriptome level, to determine when changes in gene expression take place and how they differ in worms from mixed sex and single sex infections. Male and female $S$. mansoni are still highly similar at the transcriptome level at 18 d.p.i. with only 38 DEGs identified between them. As pairing commences, their differences increase to 173 DEGs at 28 d.p.i. and continues to 2194 DEGs at 35 d.p.i. when sexual maturation of the female worms has significantly progressed. Both male and female worms expressed genes involved in the cytochrome P450dependent drug metabolism pathway at higher levels at 18 d.p.i. than at later time points. Of these genes, glutathione S transferases (including Smp_024010 and Smp_102070) in particular are thought to play a key role in the mediation of xenobiotic metabolism in schistosomes, and have been shown to bind praziquantel at a non-substrate site (Cardoso et al., 2003). Their high expression levels at the earliest point during the time course suggests that these glutathione S transferases may be responsible for the resistance of immature worms to praziquantel. Expression of genes involved in spermatocyte production such as the testes expressed transcription factors boule (Smp_144860) and basonuclin 2 (Smp_138350) was found to change from 18 d.p.i. onwards in male worms. The expression of boule, which in Schmidtea mediteranea is responsible for meiotic progression of male germ cells, rose significantly over the following time points. In contrast, the expression of basonuclin 2, which prevents premature maturation of spermatocytes in mammals, was found to decline significantly after 18 d.p.i.

Relatively few differences were found between males of mixed sex and single sex infections during their development. A notable exception to this was an aromatic-L-amino acid decarboxylase (AADC) described by Wang et al. (2017) (see above). Female worms are well known to up-regulate fertility related genes such as eggshell proteins and tyrosinases once paired, and this was observed consistently from 28 to 38 d.p.i. in mixed sex infections. A large number of transcription factors became down-regulated around the time pairing commences in females from both mixed sex as well as single sex infections. This is interesting because it showed that the down-regulation occurs in a pairingindependent fashion (Chapter 3.2.5). After an approximately three week period of maturation the female worms become developmentally arrested, which coincides with this down-regulation of transcription factors. Only after pairing, three zinc-finger transcription factors (Smp_166560, Smp_087320 and Smp_095350) became up-regulated. Their homologues in D. melanogaster regulate expression of neuropeptides (Vogler \& Urban, 2008) and the response to stimuli such as growth factors (Baou et al., 2009). If this function were conserved in schistosomes it would potentially allow them to regulate the development of female schistosomes to reach sexual maturity.

## In vitro culture has significant effects on neural genes

Having examined the process of maturation in Chapter 3, Chapter 4 aimed to examine the opposite: regression of female worms in the absence of a male partner. However, when comparing RNA-Seq data of paired and single worm, it became apparent that in vitro culture has an extensive effect on gene expression. Changes due to in vitro culture, especially of fertility related genes, had been
expected in female worms as reported in the literature (Galanti et al., 2012). However the changes in gene expression measured here were neither limited to fertility related genes nor to female worms. Using RNA-Seq the whole transcriptome could be examined rather than being limited to small numbers of genes as in previous studies. As a result a large group of neural genes involved in regulating the development of the nervous system was found to be up-regulated in vitro. These genes, such as semaphorins and their plexin and neuropilin receptors, netrins and the DCC and UNC5 receptors, slit and its robo receptors as well as ephrin and its receptors, have all been implicated in the pruning of axons and controlled neural cell death (Vanderhaeghen \& Cheng, 2010). On the other hand, neuron survival genes, such as those coding for motor neuron 1 and fragile X mental retardation protein 1, were found to be down-regulated. Together these expression results suggested that parts of the worm nervous system regressed together with the reproductive tissues. This may be of particular interest as the nervous system is thought to be involved in the regulation of female fertility (Collins et al., 2010; Wang et al., 2017).

## The role of CD63 receptor and antigen in female fertility

The analysis of RNA-Seq data revealed the up-regulation of two tetraspanins in females from mixed sex infections from 28 d.p.i.: CD63 receptor, previously reported by Fitzpatrick et al. (2009), and CD63 antigen. Using RNA-Seq and qRTPCR data, mature paired females were shown to express the CD63 receptor and antigen at 800 - and 50 -fold higher levels than male worms as well as at over 190- and 39-fold higher levels than females from single sex infections. Also, both genes were found to be depleted in the ovaries of paired females, compared to
whole worms and the in situ experiments showed expression predominantly in the vitellarian tissue. Furthermore, in Chapter 3, both genes clustered with several well-known fertility related genes strongly suggesting a role in the development or maintenance of female fertility. RNAi provided some evidence of a RNA knock down affecting egg production. However, the RNAi experiment was performed in vitro and was therefore confounded by the associated problems of reduced fertility in the negative control. Female fertility is particular difficult to study in vitro, as regression of female reproductive tissues occurs quickly outside the host although Galanti et al. (2012) showed that this process is slowed in the presence of male worms. Although only a moderate reduction of expression was achieved for the CD63 antigen and no significant reduction for the CD63 receptor, both knockdowns were found to result in a significantly reduced production of eggs (CD63 antigen: 9.6-fold; CR63 receptor: 3.2 -fold), compared to the negative control.

Given this evidence, a role of both CD63 receptor and antigen in egg production seems near certain. However, their exact function in this process is unclear. In humans the CD63 receptor is involved in forming signalling complexes of integrins and growth factors and thereby regulating downstream gene expression and cell proliferation. If the schistosome homologues performed similar functions, such a role could be crucial to regulate the development of vitellarian tissue in paired female worms. Furthermore, both the CD63 receptor and antigen have been implicated in the regulation of cell survival by downregulating integrin $-\beta$ signalling and consequently down-regulating apoptosis in human cell lines. Up-regulation of these two genes in paired females could allow
for proliferation of vitellocytes by reducing the rate of apoptosis in this tissue. The CD63 receptor has also been associated with intracellular vesicles and regulation of protein transport in and out of such vesicles. During their maturation vitellocytes become filled with intracellular vesicles in which precursors of the egg shell proteins are stored. This could mean that CD63 receptors play a role in the formation of such vesicles.

To further explore the role of CD63 receptor and antigen it would be useful to study their interactions with other proteins or maybe even with one another. This might be possible by using a yeast two-hybrid assay which has been used identify other protein interactions in S. mansoni (Vanderstraete et al., 2014). Anotherpossible method might be the use of fluorescence resonance energy transfer to observe co-localisation of CD63R and CD63a, however this would require the availablitliy of anitbodies with binding specificity to the schistosome genes. A similar approach has been used successfully before to study the interaction of tetraspanins with other proteins (Termini and Gillette, 2017).

## Apoptosis in S. mansoni

Finally, in Chapter 5, gene expression in the gonads of worms from mixed and single sex infections was examined. This enabled a set of genes to be produced with ovary- and testes-biased expression and the effect of pairing in the worm gonads to be analysed, which had previously been obscured by the somatic tissue. Several apoptosis genes have been identified in schistosomes previously and apoptosis has been shown to play an important role in regulating the growth of vitellarian tissue. In Chapter 2, many genes were examined for their sequence
homology and the presence of appropriate domains in particular, to expand the list of schistosome apoptosis genes. Among the 15 identified genes were homologues of the FAS associated factors 1 and 2, a homologue of the tumour necrosis factor receptor as well as two Bax inhibitors, adding considerable detail to how apoptosis potentially functions in S. mansoni. Having divided these genes in to pro- and anti-apoptotic genes based on the reported functions of orthologs, the expression of such genes was observed in several experiments. No consistent pattern of apoptosis related genes was found in vitro (see Chapter 4). However, a significant down-regulation of putative pro-apoptotic genes and, vice versa, an up-regulation of putative anti-apoptotic genes was observed in the ovaries of females from mixed sex infections, compared to ovaries from single sex infections (see Figure 5.17). This further strengthened my confidence that these genes are involved in the regulation of apoptosis in S. mansoni.

## The limitations of bulk RNAseq

RNA-Seq is a powerful method to study gene expression, making it possible to measure changes in mRNA levels for all genes at once. And as discussed in the introduction (see Chapter 1.6.3), RNA-Seq offers some significant advantages over other methods used to measure gene expression. However, there are also some limitations to RNA-Seq as used in this thesis. For one, studies by Schwanhaeusser et al. (2011) and Vogel et al. (2010) found the steady-state mRNA concentrations to only explain between one and two thirds of the variation in observed protein levels. However, work by Li et al. (2014) showed that due to problems with the normalisation of proteomics data in the aforementioned studies, mRNA may explain around $84 \%$ of protein abundances.

Furthermore, the correlation of mRNA and protein abundance were shown to correlate strongly when specifically looking at changes in gene expression, meaning that the mRNA abundance of differentially expressed genes is in fact very well correlated to their protein products (Koussounadis et al. 2015).

Another limitation is the use of RNA-Seq on mRNA extracted from whole worms, rather than individual organs or even single cells, although this was done to some extent in Chapter 5 of this thesis. When examining genes that are only or predominantly expressed in a subset of organs, changes in gene expression may be more difficult to detect. This is because in a sample derived from a whole worm, the mRNA of such organ-specific genes will make up a lower proportion of total reads. Another variation of this problem occurs when comparing samples from different developmental stages. As organs such as the vitellarium develop, they start to make up an increasingly large share of the sequenced mRNA. Due to this, it may appear that certain genes in these female worms have become downregulated, when in reality the absolute expression has not changed but the gene's mRNA now makes up a relatively smaller proportion of the total mRNA pool. For instance in Chapter 3.2.8, the reads from just 27 genes, most of which are known to be expressed in vitellarian cells, made up $>14 \%$ of the transcriptome of mature females. As a result many other genes appeared to be expressed at lower levels in mature females compared to females from single sex infections. Lastly, when performing RNA-Seq on whole worms, in essence the average gene expression across all tissues is measured, despite there potentially being considerable variation in expression in organs or even adjacent cells. In such samples the average of gene expression in all tissues may show a different
qualitative trend than when all tissues had been measured individually, an effect known as Simpson's paradox (Trapnell et al., 2014). Although RNA-Seq data from different tissues or even single cells would provide an even better and set of data with greater resolution of schistosome transcriptome, RNA-Seq data derived from whole worms still holds a wealth of information. Arguably, for genes expression in a single tissue, such as many genes expressed in the reproductive organs, there must be a very strong change in expression for it to be detected as significantly expressed.

As the above summary of results shows, the work in this thesis succeeded in generating high quality RNA-Seq data that illuminate the changes in gene expression that result in female maturation, following their development from approximately one week before pairing occurs to sexual maturity. The data generated here also covered transcriptome changes in vitro as well as gene expression in the gonads of male and female worms. The analysis presented in this thesis also showed numerous examples of differences between male and female schistosomes during their development as well as the changes induced by the male-female interaction.

In the future, the use of single cell RNA sequencing (scRNA-seq) could address some of the shortcomings of bulk RNA-seq. Most importantly, it would provide a finer resolution of gene expression, not providing transcriptome data of whole worms or individual organs but of single cells. With this technology, it could be possible to detect and quantify the abundance of mRNAs coding for the CD63 receptor and antigen in different subpopulations of vitellocytes. The vitelline
tissue could be dissociated using a collagenases or dispases (Freshney, 1987) and fluorescence activated cell sorting (FACS) could be used to sort cells by their granularity (Basu et al., 2010). This may allow vitelline S1, S2, S3 and S4 cells to be separated as they contain increasing numbers of vesicles (Erasmus, 1975), with S4 cells being most densely packed with eggshell protein containing vesicle (Köster et al., 1988). With this method the localisation of CD63R to particular portion of the vitellaria could potentially be confirmed. Also, very small subpopulations of cells could potentially be examined, such as stem cells, which have previously been observed (Collins et al., 2013), and could play a role in the ability of $S$. mansoni to regenerate reproductive tissues after losing it. Similarly, scRNA-seq could provide unprecedented resolution of the development of cells in the ovary and testes. This may make it possible to better understand the role of apoptosis in the development of ovarian tissue.

However, not all of the goals of this thesis could be met. In particular, examining the regression of sexually mature females as a result of separation from male worms in Chapter 4 proved challenging. Despite several biological replicates, the number of differentially expressed genes found between treatment groups was low. This most likely resulted from the large magnitude of transcriptome changes brought on by in vitro culture, which was shown to have extensive effects on the transcriptome of male and female worms. Due to this, the focus of the chapter changed to examining the effects of in vitro culture on gene expression, especially neural and apoptosis-related genes. The transcriptome changes observed in Chapter 4, most likely brought on by a lack of host factors, highlights the need for a better in vitro culturing system. Alternatively, worms
could have been re-implanted into mice (Basch \& Humbert, 1981) after separation from their partner, to provide a host environment for the rest of the experiment. However, this method would have required more mice to be subjected to invasive procedures, moreover it would expose the worms themselves to considerable stress, which might have interfered with gene expression. Another improvement could have been to perform the RNAi experiment described in Chapter 3 in vivo, as described by (Wang et al., 2017). As described above, the in vitro conditions caused changes in gene expression that made it difficult to detect the changes in gene expression brought on by the dsRNA treatment compared to the control. Performing RNAi in vivo circumvents that problem by making in vitro culture during or after exposure to dsRNA unnecessary.

The results in this thesis, including a better understanding of the male-female interaction as well as how apoptosis functions in schistosomes, will hopefully prove valuable for the development of therapeutics in the future. For example, in addition to GST28 (Smp_054160), a long-standing vaccine target, other glutathione S transferases, such as Smp_024010, may also be suitable therapeutic targets. Also an improved understanding of how schistosomes regulate apoptosis could make it possible to exploit differences between schistosome and mammalian apoptosis to kill worms. The data generated for Chapter 5, in collaboration with Professor Grevelding's group, has also been made available to the research community as a resource for gene expression data in the gonads of adult male and female worms (Lu et al., 2017).

To further investigate apoptosis in the ovaries, but also the vitelline tissue, a number of approached could be taken in the future.

To determine how much apoptosis is taking place in the ovaries of females from MS and SS infections, terminal deoxynucleotidyl transferase dUTP nick end labelling (TUNEL) staining could be used, as Galanti et al. (2012) did to detect apoptosis in the vitelline tissue. TUNEL staining is a method that detects the DNA fragmentation that occurs during apoptosis (Kyrylkova et al., 2012). This is done by using the terminal deoxynucleotididyl transferase to conjugate labelled nucleotides, for example with a bromodeoxyuridine (BrdU) label. In the next step, these nucleotides can then be detected with a method appropriate for the chosen label (Kyrylkova et al., 2012). In the case of BrdU, this can be done with antibodies with conjugated alkaline phosphatase, allowing BrdU detection using a method like that used in WISH (Chapter 2.2.7). Another method which could be used to study apoptosis is an assay for caspase 3 activity (Galanti et al., 2012).

In Chapter 5, differences in the expression of gene coding for proteins of the sphingolipid metabolite pathway were observed in the ovaries of females of SS and MS infections. Two important enzymes regulating the abundance of ceramide in cells are ceramide synthase and ceramidase (Levy \& Futerman, 2010; Mullen et al., 2012). Inhibitors of these enzymes could be used to investigate if these enzymes also play a role in regulating apoptosis in S. mansoni, as they do in mammalian cells (Separovic et al., 2012; Zhu et al., 2008). Fumonisin B, a fungal toxin, has been shown to inhibit ceramide synthase and reduce apoptosis in human cells (Boppana et al., 2014), whereas carmofur is a
potent ceramidase inhibitor (Realini et al., 2013). Using TUNEL staining, it may be possible to examine, if an effect on apoptosis can be observed in females from SS and MS infections when exposed to these inhibitors. Treatment of females from SS infections may prevent apoptosis of vitellarian cells and allow maturation of the organ. On the other hand, treatment of females from MS infections with carmofur, may result in higher levels of apoptosis and lead to a shrinkage of the vitellarian tissue.

There are also fluorescence-based assays available to measure the activity of ceramide synthase (Kim et al., 2012) and ceramidase (Bedia et al., 2010), which could be used to confirm the specificity of the inhibitors to the schistosome homologues of these genes.

By addressing the limitations discussed above, new insights can be gained. Single cell RNA-Seq especially will open up new avenues for characterising gene expression at much greater resolution and improve our understanding of schistosome biology. Secondly improving the available in vitro culture methods will allow for better characterisation of genes, which may become targets for future interventions.

Appendix A.1: Summary of sequencing statistics for sequnced RNA-Seq samples. Samples names provide the day post infections (e.g. D18 stands for 18 d.p.i.), the gender and replicate number (e.g. F1 is female replicate 1) and the pairing status (MS for mixed sex infections, SS for single sex infection). Total reads is the number of all reads sequenced. Mapped is the total number of reads mapped to the $S$. mansoni reference genome v5.2. 'Prop. Paired' refers to the total number of reads mapped together with a mate-paired read in close proximity and in the correct orientation. Unmapped is the total number of reads that could not be mapped to the reference by Tophat2.

Appendix A.6: Expression of genes encoding neurotransmitters in females compared to males from single sex infections at $\mathbf{3 8}$ days post infection. Fold changes measure expression in male relative to female worms; that mean genes with a fold change of $>1$ are up regulated in males. The $p$-value has been adjusted for multiple hypothesis testing.

| Pathway | Description | Total <br> Genes | DEGs | Expected | p-value |
| :--- | :--- | ---: | ---: | ---: | ---: |

Appendix A.7: KEGG pathways which are significantly enriched amongst the genes up regulated in males from single sex infections at 18 days post infection compared to males at 21 days post infection. "Total genes" is the number of genes in the given pathway. "DEGs" provides the number of differentially expressed genes in that pathway. "Expected" provides the number of genes expected by chance to be differentially expressed in each pathway.

| Comparison | Fold change | Adjusted p-value |
| :--- | ---: | ---: |
| Expression in males worms at 18 d.p.i. <br> compared to males at 21 d.p.i. | 5.10 | $6.45 \mathrm{E}-06$ |
| Expression in males worms at 18 d.p.i. <br> compared to males at 38 d.p.i. | 21.95 | $1.34 \mathrm{E}-14$ |
| Expression in females worms at 18 d.p.i. <br> compared to females at 38 d.p.i. | 18.16 | $1.30 \mathrm{E}-11$ |

Appendix A.8: Expression of the gene encoding the microsomal glutathion $S$ transferase (Smp_024010) in different gene expression comparisons of male and females worms at different time points. The fold change provides the gene expression in the first condition relative to the second condition in each comparison. Smp_ 024010 was found up-regulated in male or female worms at 18 days post infection (d.p.i.) compared to later time points in all the comparisons. The $p$-value has been adjusted for multiple hypothesis testing.

Appendix A.18: List of genes from Appendix A. 17 expressed in female worms from single sex infections at 21 days post infection (d.p.i.) compared to females at 28 d.p.i. These genes are involved in the regulation of transcription (annotated with GO term G0:0006355). The fold change provides a measure of gene expression in females from single sex infections at 21 d.p.i. compared to females at 28 d.p.i. The $p$-value has been adjusted for multiple hypothesis testing.

| Gene ID | Product | Fold change | Adjusted $p$-value |

Appendix A.19: The most differentially expressed genes in females from mixed sex infections at $\mathbf{3 8}$ days post infection (d.p.i.) compared to females at 18 d.p.i. Three putative transcription factor genes (Smp_095350, Smp_087320 and Smp_166560) were added to this list despite ranking lower on the list of most differentially expressed genes but are in the 100 most differentially expressed genes. Fold changes provide a measure of gene expression in females at 38 d.p.i. compared to females at 18 d.p.i. The $p$-value has been adjusted for multiple hypothesis testing.

Appendix A.20: Expression of genes of Cluster 13 from the Kohonen analysis in the comparison of female worms from mixed sex infections to males worms at 38 days post infection. Fold changes provide a measure of gene expression in females worms relative to male worms. The $p$-value has been adjusted for multiple hypothesis testing. The Rank provides the position of the gene within the list of differentially expressed gene when ordered by fold change. All genes in Cluster 13 where amongts the 40 most differentially expressed genes. The final column indicates the presence or absence of a trematode eggshell synthesis domain in the encoded protein.

Appendix A.24: Summary of the 76 genes in Cluster 7 generated by MBCluster. The column "Average read count" provides a measure of absolute expression, the average number of reads mapped to the gene across all RNA-Seq samples used in Chapter 3. The fold changes provided reflect expression in females from mixed sex infections compared to females from single sex infections at 38 days post infection.

Appendix A.25: Significantly enriched GO terms amongst the genes in Cluster 7 of the MBCluster analysis. "Annotated" provides the total number of genes in the genome annotated with a given GO term. "Significant" provides the number of genes annotated with that GO term in Cluster 9. "Expected" provides the number of genes with that GO term expected by chance. The significance cutoff was $\mathrm{p}=0.01$.

Appendix A.26: This table provides the $C_{T}$ for all of the qRT-PCR reactions used to measure gene expression the RNAi knockdown expreiment using the soaking method. Three PCR replicates are given for each combination of target gene and treatment replicate (e.g. CD63R 1 and CD63 R2). $C_{T}$ were not determined beyond 40 cycles of replication; samples that did not show amplification were assigend " $>40$ " as $C_{T}$ value. For each sample replciate a negative control was run which had not been reverse transcribed to detect gDNA contamination in the total RNA extracted from the worms. Another negative control with out any added template was run together with the samples.

Table B.1: Summary of sequencing statistics for sequnced RNA-Seq samples. Total reads is the number of all reads sequenced. Mapped is the total number of reads mapped to the S. mansoni reference genome v5.2. 'Prop. Paired' refers to the total number of reads mapped together with a mate-paired read in close proximity and in the correct orientation. Unmapped is the total number of reads that could not be mapped to the reference by Tophat2.

## Apoptosis-related proteins

14-3-3 proteins play an important role in relaying apoptosis signals within cells and exert pro-apoptotic effects at different points of the apoptosis pathway (Rosenquist, 2003). Three 14-3-3 proteins have been annotated in S. mansoni all of which were found to contain a 14-3-3 Pfam domain as well as significant BLAST hits (Table 4.1) against 14-3-3 proteins of model organisms.

The next group of genes I examined are caspases which are key mediators of apoptosis as they form the apoptotic protease cascade that lead to controlled cell death (McIlwain et al., 2013). Four caspase homologues have been identified in $S$. mansoni, which all contain a caspase domain. Blast results suggest caspase-3, -7 and -8 homologues are represented in the S. mansoni genome. Three of these caspases (Smp_028500, Smp_141270 \& Smp_032000) were previously described by Lee et al. (2014).

Figure B.2: Diagram of 14-3-3 family members showing length and presence of PFAM domains.

Figure B.3: Diagram of caspase family members showing length and presence of PFAM domains.

Another group of proteins that function as regulators of apoptosis, in both proand anti-apoptotic roles are $\mathrm{Bcl}-2$ domain containing proteins. Four $\mathrm{Bcl}-2$ domain containing proteins were identified by InterProScan, a further two were found to be annotated as Bcl-2 proteins, one in the genome (Smp_041630)
(Protasio et al., 2012) and the other by Lee et al. (2011) (Smp_043360). However InterProScan did not identify $\mathrm{Bcl}-2$ domains in the later two, nor did BLAST find significant homology to such proteins (Table B.5), which is why I decided to exclude them from the down-stream work flow of my analysis. One of the genes identified by InterProScan showed significant homology to apoptosis regulator Bax, also known as Bcl-2-like protein 4, a known pro-apoptotic member of the bcl-2 like family (Pawlowski \& Kraft, 2000). Five of the Bcl-2 family proteins (Smp_043360, Smp_072180, Smp_095190, Smp_213250 \& Smp_168470) were described previously (Lee et al., 2014).

Figure B.4: Diagram of Bcl-2 domain containing protein showing length and presence of PFAM domains. Two genes, marked with ' X ', failed the quality control and were excluded from the following analysis.

Two genes were found to contain Bax-Inhibition domains. Bax is known to have an important pro-apoptotic domain and its activity is tightly regulated by proteins such as Bax inhibitor 1. This group of proteins was first identified as an inhibitor of Bax but was later recognised to inhibit apoptosis through interactions with several other pro-apoptotic processes as well (Robinson et al., 2011).

Figure B.5: Diagram of BAX interacting proteins showing length and presence of PFAM domains.

The Fas ligand:receptor interaction was one of the first aspects of the proapoptotic signalling cascade to be studied (Nagata, 1997, 1999). A homologue of the Fas receptor as well as several homologues of Fas associated proteins with putative roles in the regulation of apoptosis have been identified. Determining whether these genes should be assigned putative pro- or anti-apoptotic function based on domains was difficult as two of the genes did not contain known domains (see Figure B.7) so that their function could only be inferred by
homology to genes of model organisms. However the function of the human fas binding factor 1 (FAB1) and fas associated factor 2 (FAF2) are only poorly understood. FAF2 is thought to confer resistance to apoptosis to T cells in patients with atopic dermatitis (Koelsch et al., 2013). FAB1 on the other hand was first described in 2000 but no definitive function has yet been assigned (Schmidt et al., 2000).

Figure B.6: Diagram of Fas receptor and associated proteins, showing length and presence of PFAM domains.

Figure B.7: Diagram of inhibitor of apoptosis protein, showing length and presence of PFAM domains.

The schistosome homologue of the Inhibitor of Apoptosis protein (IAP) was identified by Peng et al. (2010) and contains two overlapping "cytokine induced apoptosis inhibitor $1^{\prime \prime}$ domains, but lacks the Baculo virus IAP repeat (BIR) domain which is a hallmark of the family of IAPs. Rather than a member of the IAP family, Smp_207000 shares greater sequence similarity with the human anamorsin gene, a cytokine induced inhibitor of apoptosis. Given that the schistosome homologue was shown to inhibit caspases and thus apoptosis both in human cells as well as schistosome lysate (Peng et al., 2010) it can be classified confidently as an anti-apoptotic gene.

Figure B.8: Diagram of cathepsin D homologues, showing length and presence of PFAM domains.

Cathepsin D is a lysosomal protease that besides its role in digestion also plays a regulatory function in apoptosis. When activated, for example by ceramide (Heinrich et al., 1999), cathepsin D mediates oxidative stress induced apoptosis by translocation to the cytoplasm (Watchorn et al., 2001) as well as mediation of cytochrome C release and caspase activation (Conus et al., 2008; Johansson et al.,
2003). Both cathepsin D homologues in S. mansoni contain aspartate protease domains as expected from cathepsins.
p21 is a cyclin dependent kinase (CDK) inhibitor and an important regulator of cell fate, controlling both division and apoptosis depending on the cell state and extracellular signals. By impeding CDKs it can arrest the cell cycle and is considered an important proliferation inhibitor (Gartel \& Tyner, 2002). Despite this, p21 is a negative regulator of p53-dependent apoptosis. p21-activated kinase 1 (PAK1) are serine/threonine protein kinases serving as mediators of Rac and Cdc42 GTPase function as well as Ras-driven tumorigenesis by protecting cells from apoptosis (Ong et al., 2011). As the schistosome homologue of PAK1 has a protein kinase domain as well as significant sequence similarity to the human PAK1, I assigned it a putative anti-apoptotic function. The PAK1 interacting protein (PAK1IP) homologue on the other hand contains a conserved WD40 repeat, as does the human PAK1IP. PAK1IP is a negative regulator of PAK1, binding to the N-terminal region of PAK1 to inactivate it, thus acting in a pro-apoptotic function (Xia et al., 2001).

Figure B.9: Diagram of PAK1 and PAK1IP, showing length and presence of PFAM domains.

Five other $S$. mansoni genes were found to be homologous to apoptosis regulating genes of humans and C. elegans. These did not form a related group of genes and thus contain a range of different, unrelated protein domains, such as WD40, SH2 and Sh3 domains. The apoptotic protease activating factor (APAF1) like gene (Smp_140260) contains several WD domains that allow its human and C. elegans homologues to bind to caspase proteins and activate them, thereby promoting apoptosis (Qin et al., 1999; Yakovlev et al., 2001). The schistosome homologue of APAF1 (Smp_140260) was first described by Lee et al. (2014).

Almost the entire length of the schistosome homologue of apoptosis inhibitor 5 (AIP5) is made up of a conserved apoptosis inhibitory protein 5 domain, which, together with the sequence homology to human AIP5 suggests that it has an antiapoptotic effect, acting as a suppressor of E2-promoter binding factor dependent apoptosis (Morris et al., 2006).

In humans, the apoptosis inducing factor 1 is associated with the mitochondria and involved in a caspase independent activation of apoptosis (Joza et al., 2001; Susin et al., 1999). The schistosome homologue (Smp_137540) shares a "Cterminal mitochondrion-associated apoptosis-inducing factor"-domain as well as a pyridine nucleotide-disulphide oxidoreductase domain.

Like the human apoptosis-stimulating of p53 protein (PPP1R13B), the schistosome homologue has two domains near its C-terminus: an ankyrin repeat and a SH3 domain. In humans, these domains allow PPP1R13B to interact with p53/TP53 and regulate it by enhancing the DNA binding and transactivation function of TP53 on the promoters of pro-apoptotic genes in vivo, thereby specifically enhancing apoptosis but not cell cycle arrest (Samuels-Lev et al., 2001).

Figure B.10: Diagram of miscellaneous apoptosis related proteins, showing length and presence of PFAM domains.

Appendix B11: All 150 genes found to be differentially expressed between paired and separated females 8 days after perfusion. Genes are ranked by adjusted p-value, from smallest to largest. Average read count provides a measure of absolute expression. The fold change is expression in separed females, relative to paired females. The $p$-value has been adjusted for multiple hypothesis testing.

Appendix C.1: Summary of sequencing statistics for sequnced RNA-Seq samples. Samples are named as follows: Sample type (Males - M; Female - F; Testes - T; Ovaries - 0), replicate number (1 to 3) and infection status (Mixed sex infections - MS; Single sex infection - SS). Total reads is the number of all reads sequenced. Mapped is the total number of reads mapped to the Schistosoma mansoni reference genome v5.2. 'Prop. Paired' refers to the total number of reads mapped together with a mate-paired read in close proximity and in the correct orientation. 'Singletons' refers to the total number of reads with a correctly mapped mate but themselves unmapped. Unmapped is the total number of reads that could not be mapped to the reference by Tophat2. Mapped to feature is the total number of reads mapped to exons of annotated genes in the reference, excluding introns as well as $5^{\prime}$ - and 3 '-UTRs.

Appendix C.2: Bioanalyzer data shows that ovary and whole male worm samples form single sex infections had good quality total RNA. RNA was extracted from whole worms and isolated organs and the quality examined as described in Chapter 2.2.3. All samples showed a single, sharp ribosomal RNA peak and no signs of degradation.

Appendix C.3: List of genes examined in Chapter 5.2.2. Expression data is provided for the comparison of ovaries from females from single sex (SS) infections compared to the ovaires from mixed sex (MS) infections. Average read counts provide a measure of absolute expression for a given gene. The fold changes reflect expression in ovaries from SS females relative to ovaires of MS females. The $p$-value has been adjusted for multiple hypothesis testing.

Appendix C.6: Expanded list of DEGs with testes-biased expression compared to whole males. Average read counts are a measure of absolute gene expression; they are the average of normalised read counts across all RNA-seq samples used in Chapter 5. The fold changes reflect expression in the testes relative to whole male worms. The $p$-value has been adjusted for multiple hypothesis testing.

Appendix C.12: Expanded list of GO terms enriched amongst the genes upregulated in ovaries of females from mixed sex infections compared to whole females. The column "Total Genes" provides the number of genes associated with a particular GO term. "DEGs" provides the number of genes associated with a given GO term that had significantly higher expression in ovaries of females from mixed sex infections; "Expected Genes" provides the number of differentially expressed genes associated with a given GO term that are expected by chance.

| Pathway | Description | Total Genes | DEGs | Expected | p-value |
| :---: | :---: | :---: | :---: | :---: | :---: |

Appendix C.13: Complete list of KEGG pathways enriched amongst the genes upregulated in the ovaries of females from mixed sex infections compared to whole females. The column "Total Genes" provides the number of genes in the KEGG pathway. "DEGs" provides the number differentially expressed genes in that pathway; "Expected Genes" provides the number of differentially expressed genes in a given pathway that is expected by chance.

| Domain | Description | Total <br> Genes | DEGs | Expected | p-value |
| :--- | :--- | :---: | :---: | :---: | :---: |

Appendix C.17: Genes up-regulated in whole males from mixed sex infections compared to testes. Average read counts are a measure of absolute expression across all samples, and fold changes provided a measure pf gene expression in whole males relative to testes. The $p$-value has been adjusted for multiple hypothesis testing.

| Comparison | Fold Change | Adjusted p-value |
| :--- | ---: | ---: |
| Expression in ovaries from single sex infections <br> compared to ovaries from mixed sex infections | 9.07 | $8.58 \mathrm{E}-12$ |
| Expression in females from single sex infections <br> compared to females from mixed sex infections | 12.34 | $9.46 \mathrm{E}-31$ |

Appendix C.18: Expression of the gene encoding follistatin (Smp_122300) in female worms and their ovaires. The first column specificies the samples in which expression of Smp_122300 was compared. The fold change provides a measure of gene expression in the first sample compared to the second. Smp_122300 expression was up regulated in the single sex sample in both cases. The $p$-value has been adjusted for multiple hypothesis testing.

Appendix C.24: Expression of putative apoptosis related genes in the ovaries of females from single sex infections, compared to ovaries from mixed sex infections. The fold change provides a measure of expression in the ovaries of ovaries from single sex infections compared to those from mixed sex infecitons (That means fold changes greater than 1 indicate an up regulation in the ovaries from single sex infections). The $p$-value has been adjusted for multiple hypothesis testing.

| PF01221 | Dynein light chain type 1 | $7141 \mathrm{E}-03$ |  |  |
| PF00520 | Ion transport protein | 43 | 15 | 8.61 |
| PF09379 | FERM N-terminal domain | 19 | 11.94 | $8.619 \mathrm{E}-03$ |
| PF00373 | FERM central domain | 19 | 10 | 5.28 |
| PF00617 | RasGEF domain | 9 | 6 | 2.50 |
| PF03133 | Tubulin-tyrosine ligase family | 9 | 6 | 2.50 |
| PF07714 | Protein tyrosine kinase | 46 | 19 | 12.78 |
| PF07690 | Major Facilitator Superfamily | 43 | 18 | 11.94 |
| PF00754 | F5/8 type C domain | 7 | 5 | 1.94 |
| PF00501 | AMP-binding enzyme | 12 | 7 | 3.33 |
| PF01391 | Collagen triple helix repeat (20 copies) | 12 | 7 | 3.33 |
| PF00036 | EF hand | 3 | 3 | 0.014 |
| PF00992 | Troponin | 3 | 3 | 0.017 |
| PF01596 | O-methyltransferase | 3 | 3 | 0.020 |
| PF03188 | Eukaryotic cytochrome b561 | 3 | 0.83 | 0.021 |
| PF04434 | SWIM zinc finger | 3 | 0.83 | 0.021 |
| PF04712 | Radial spokehead-like protein | 3 | 3 | 0.83 |

Appendix C.27: Expanded list of Pfam domains enriched amongst the genes up-regulated in ovaries of females from single sex infections compared to those of mixed sex infections. The column "Total Genes" provides the number of genes encoding a given Pfam domain. "DEGs" provides the number of differentially expressed genes with that domain; "Expected" provides the number of differentially expressed genes with a given domain that is expected by chance.
