# The pre-clinical evolution of haematological malignancies

Grace Collord King's College University of Cambridge

This dissertation was submitted for the degree of Doctor of Philosophy August 2019.

## Declaration

I hereby declare that this dissertation is my own work and that any work done in collaboration with others is explicitly indicated in the text. This work does not contain any material substantially similar to work I have previously submitted, or am in the process of preparing, for any qualification at any institution. This dissertation does not exceed 60,000 words in length.

Grace Collord August 2019

### Summary

### The pre-clinical evolution of haematological malignancies

### Grace Collord

Cancer-associated somatic mutations frequently drive clonal expansions in normal ageing tissues. However, the factors governing whether pre-cancerous cells transform into cancer are poorly understood, hindering identification of clones that are clinically significant rather than benign sequelae of ageing. The main aim of this dissertation has been to explore this process in the haematopoietic system, where leukaemia-associated mutations are detectable in >10% of individuals over the age of 50. This phenomenon, termed clonal haematopoiesis (CH), is associated with an increased risk of blood cancers, though only a small minority of individuals progress.

Acute myeloid leukaemia (AML) is the commonest acute leukaemia in adults, and usually presents abruptly with complications of bone marrow failure. Using deep targeted sequencing of stored blood DNA samples from individuals who went on to develop AML and controls, we identified features of CH that predict leukaemic progression. The number, type and burden of genetic changes, as well as certain clinical variables, were predictive of AMLfree survival. Examining the pre-clinical evolution of lymphoid malignancies using a similar study design and broader sequencing approach also revealed genetic and clinical features predictive of malignant transformation.

The final part of this study investigates the prevalence of clonal haematopoiesis in childhood cancer survivors treated with intensive chemo- or radiotherapy. In contrast to adult cancer patients, the prevalence of CH in children is not dramatically increased by cytotoxic treatment.

Collectively, these findings provide proof of principle that benign and pre-malignant clonal expansions in normal blood (and perhaps other tissues) may be distinguishable years prior to overt malignant transformation. This could in future enable earlier detection of those at high risk of blood cancers, and stimulate research into possible interventions to reduce the risk of progression.

### Acknowledgements

I would like to thank our collaborators for decades of work collecting and curating patient samples and metadata, in particular the European Prospective Investigation into Cancer and Nutrition (EPIC) study, as well as Professor Francesco Frassoni (Instituto Giannina Gaslini, Italy), Dr Kris Bowles (Norfolk and Norwich University Hospital, UK), the Norwich Research Park Biorepository (UK), Dr Matthew Murray (University of Cambridge), Dr Anna Godfrey (University of Cambridge), Dr Amy Jones (Cambridge Haematopathology and Oncology Diagnostic Service), Kevin Jestice (Cambridge Cellular Therapy Laboratory) and Dr Joanna Baxter (Cambridge Blood and Stem Cell Biobank, UK). In particular, Robert Luben and Shabina Hayat of the EPIC-Norfolk study team were instrumental in enabling the work described in chapters 3 and 4. I am indebted to many colleagues for discussions and advice, in particular Dr Naomi Park, Dr Peter Campbell, Dr Inigo Martincorena and Dr Ignacio Varela. I would particularly like to thank Dr Moritz Gerstung for imparting most of what I know about statistics and Dr Sam Behjati, Dr Patrick Tarpey and Dr Elli Papaemmanuil for teaching me to navigate the cancer genome. I would like to thank my supervisors, Dr George Vassiliou and Professor Mike Stratton, for giving me the opportunity to pursue this work in an exceptionally collaborative research environment. I am grateful to King's College and to the funders who have generously supported this work, particularly the Wellcome Trust.

## Chapter 1 Introduction

Modern sequencing technologies are catalysing a revolution in our understanding of cancer genetics, developmental disorders, and ageing (Behjati et al., 2018; Martincorena and Campbell, 2015; Stratton, 2011; Yates and Campbell, 2012). Over the past decade, genomic scrutiny of over a million cancers has revealed the oncogenic mutations responsible for causing most human malignancies (Tate et al., 2019). These discoveries have enabled development of novel targeted cancer therapies and sequencing-based cancer diagnostic methods (Chang et al., 2016; Gerstung et al., 2017; Zahn, 2016). In parallel, sequencing of normal tissues has demonstrated that somatic mutations accumulate in all cells with age due to a host of extrinsic and endogenous exposures (Alexandrov et al., 2013; Hoang et al., 2016; Ju et al., 2017; Martincorena and Campbell, 2015; Yizhak et al., 2018). Somatic genetic diversity in ageing tissues provides a substrate for natural selection at the cellular level. Most somatic mutations have no discernible impact on cell function (Martincorena et al., 2017). However, recent studies have demonstrated that canonical cancer driver mutations are remarkably common in morphologically and functionally normal tissues and frequently fuel clonal expansion (Bowman et al., 2018; Martincorena et al., 2018; Martincorena et al., 2015; Moore et al., 2018; Salk et al., 2018; Yizhak et al., 2018; Yokoyama et al., 2019). The ubiquity of subclonal cancer evolutionary processes represents a daunting challenge to sequencingbased early cancer detection efforts and may also increase the toxicity of novel precision oncology drugs targeting cancer driver mutations present in a significant fraction of normal cells (Busque et al., 2018; Cohen et al., 2018; Martincorena et al., 2015). The landscape of somatic genetic diversity is currently best understood in the haematopoietic system, largely due to ease of representative sampling. Clonal haematopoiesis (CH) becomes increasingly common with age and is associated with an increased risk of haematological malignancies,

though only a small minority of individuals with CH ever develop a blood cancer (Busque et al., 2018). The main aim of this dissertation has been to explore the premalignant mutational landscape of haematological cancers and the extent to which indolent clones can be distinguished from CH at high risk of malignant transformation. The general introduction to this thesis provides an overview of somatic evolution in cancer and normal tissues, with an emphasis on the haematopoietic system.

### 1. Somatic evolution in cancer

"At last gleams of light have come, & I am almost convinced (quite contrary to opinion I started with) that species are not (it is like confessing a murder) immutable."

- Charles Darwin to Joseph Hooker, 11 January 1844

"One general law, leading to the advancement of all organic beings, namely, multiply, vary, let the strongest live and the weakest die.... Natural Selection, as we shall hereafter see, is a power incessantly ready for action"

- Charles Darwin, The Origin of Species, 1959

*"If, as I believe that my theory is true & if it be accepted even by one competent judge, it will be a considerable step in science."* 

- Charles Darwin to Emma Darwin 5 July 1844

As presciently anticipated by Darwin, natural selection is relevant to much more than the evolution of free-living species. The cells that make up multicellular organisms possess the requisite features for natural selection according to Darwin: heritable variation that impacts fitness. Cells, like species, are mutable, inevitably accumulating changes in their genomes due to extrinsic factors (e.g., radiation) and endogenous processes (e.g., errors in DNA replication and repair) (Alexandrov et al., 2013; Martincorena and Campbell, 2015). According to current estimates, most cells accumulate one to two mutations per cell division (Yizhak et al., 2018), though this rate may vary considerably (Hoang et al., 2016). Somatic mutations generate variety and starting from early embryogenesis, multicellular organisms become mosaics of

genetically distinct cells (Behjati et al., 2014; Blokzijl et al., 2016; Ju et al., 2017). This variety creates a substrate for natural selection. Although few somatic mutations impact cell function (Martincorena et al., 2017), occasionally a mutation confers a fitness advantage, favouring clonal expansion of the cell harbouring it (Martincorena and Campbell, 2015; Yates and Campbell, 2012). The competitive advantage conferred by a given mutation may be contextdependent, varying with environmental exposures (Bondar and Medzhitov, 2010; Wong et al., 2015b; Yates and Campbell, 2012; Yokoyama et al., 2019). Cell competition has been most extensively studied in simpler model organisms, where it is often a beneficial physiological process that helps ensure that tissues are made up of the healthiest cellular constituents (Amoyel and Bach, 2014; Baker and Li, 2008). In humans, somatic evolution has primarily been studied in the context of cancer, where the process produces a cell with a complement of mutations enabling it to escape normal constraints on proliferation and to invade other tissues (Hanahan and Weinberg, 2000, 2011). However, recent studies of somatic mutation in the context of human development, ageing, pre-cancer, cancer and non-malignant disease have indicated that the border between normal age-related somatic evolution and malignancy can be indistinct (Martincorena et al., 2018; Martincorena et al., 2015; Moore et al., 2018; Salk et al., 2018; Yizhak et al., 2018; Yokoyama et al., 2019). This introduction will provide an overview of somatic evolution in cancer and ageing with a focus on the haematopoietic system, which has been particularly well characterised due to ease of representative tissue sampling.

### 1.1 Cancer is a genetic disease

"...a malignant cell is a cell with an irreparable defect, located in the nucleus. There is a permanent change in the condition of the chromatin which forces the cell to divide."

- Theodore Boveri, 'The Origin of Malignant Tumours', 1914 (Manchester, 1995)

"I got sort of amused tolerance at the beginning."

- Janet Rowley recalling the response of the scientific community to her 1972 discovery that chromosomal translocations could cause cancer. (Fox, 2013)

The history of the mutational theory of cancer is a reminder of the power of simple experiments interpreted well and of the amount of time it can take for pivotal discoveries to elicit follow-up work and acceptance. Theodore Boveri is generally credited with being the first biologist to recognise that abnormal genetic content is responsible for malignant transformation (Rowley, 2001). His observations stemmed from meticulous light microscope scrutiny of sea urchin embryo divisions and the observation that aberrant mitoses seemed to trigger developmental defects.

"Experiments on sea urchin embryos have led to the result that most chromosome combinations that vary from the normal lead to the death of the cell; however, other combinations occur, in which the cell, while it remains viable, does not function in a typical way."

- Theodore Boveri, 'The Origin of Malignant Tumours', 1914 (Manchester, 1995)

Boveri concluded that chromosomal content guides embryogenesis and further speculated that the entities responsible for Mendelian traits must reside within chromosomes:

"I feel beyond any doubt that the individual chromosomes must be endowed with different qualities and that only certain combinations permit normal development."

- Boveri, 1901 (Hardy and Zacharias, 2005)

"The probability is extraordinarily high that the traits examined in the Mendelian experiments are linked to individual chromosomes"

- Boveri, 1914 (Hardy and Zacharias, 2005)

These conclusions led Boveri to revisit observations made over twenty years previously by David Hansemann (1858–1920), a German pathologist who had documented asymmetrical nuclear segregation in a host of human cancers (Hardy and Zacharias, 2005). Hansemann maintained that nuclear abnormalities were most likely to represent characteristic sequelae of the malignant process (Hardy and Zacharias, 2005). Boveri, reinterpreting Hansemann's findings in the context of the sea urchin experiments, posited that cancers are the progeny of a single cell that acquired uncontrolled growth potential due to abnormal chromosomal content (Hardy and Zacharias, 2005; Manchester, 1995). Boveri's hypothesis that chromosomes contained the material of inheritance was confirmed by the experiments of Avery, MacLeod and McCarty in 1944 (Avery et al., 1944). Further evidence that tumours often contain wildly bizarre chromosomes accumulated over the ensuing decades as cytogenetic methods improved. In the 1950s, Hauschka, Levan, Makino and others documented that most cancer cell lines contain aberrant chromosome numbers, as well as dicentric and ring chromosomes (Rowley, 2001). However, there was no apparent trend between particular abnormalities and cancer type, leading to further scepticism of any role in carcinogenesis (Rowley, 2001).

In the 1960s and 1970s, a clear association emerged between specific chromosomal abnormalities and particular leukaemias. In 1960, Nowell and Hungerford reported the Philadelphia (Ph) chromosome in almost all cases of chronic myeloid leukaemia (CML) (Nowell and Hungerford, 1960). Aided by improved chromosome banding techniques, Janet Rowley was able to establish that the Ph chromosome represented an interchange between chromosomes 9 and 22 (Rowley, 1973). Several other recurrent translocations were discovered in the 1970s by Rowley, Zech and others, notably the AML-associated t(8;21), t(8;14) in Burkitt lymphoma and t(15;17) in acute promyelocytic leukaemia (Rowley, 2001; Zech et al., 1976). It took until the early 1980s for the diagnostic and prognostic utility of these findings to be incorporated into clinical guidance (Rowley, 2001).

The advent of clinical cytogenetics coincided with further definitive proof that somatic mutations in DNA cause cancer. Weinberg, Cooper and colleagues demonstrated that human tumour DNA introduced into a mouse fibroblast cell caused malignant transformation (Krontiris and Cooper, 1981; Shih et al., 1981). Retrieval of the human sequence from the murine malignant cells ruled out spontaneous in vitro transformation, as can occur in many putatively normal cell lines (Krontiris and Cooper, 1981; Shih et al., 1981). Isolation of the oncogenic DNA fragment led to the discovery of an activating substitution mutation in *HRAS*, thus demonstrating for the first time that simple missense mutations, in addition to chromosomal rearrangements, can cause cancer (Reddy et al., 1982; Tabin et al., 1982). This discovery stimulated widespread concerted efforts to systematically identify genetic mutations capable of causing cancer.

Cancer gene discovery efforts further accelerated following the release of the first draft human genome sequence in 2000 (Lander et al., 2001; Venter et al., 2001) and the advent of massively parallel sequencing a few years later (Stratton, 2011; Stratton et al., 2009). The ensuing revolution in genomics has yielded unprecedented insights into the pathogenesis of cancer, as well as the inextricably related processes of human development and ageing. The next section will give an overview of some important concepts that have emerged from the study of the cancer genome.

### 1.1.1 Classifying mutations according to selection: 'driver' and 'passenger' mutations

To date, over 1.4 million tumour samples have been sequenced, including tens of thousands of whole genomes (Sondka et al., 2018). The ability to scrutinise whole genomes from diverse cancer types has revealed dramatic variation in somatic mutation burden, ranging from over 100 per megabase (Mb) in some melanomas and mismatch-repair deficient tumours to fewer than 0.01 mutations/Mb in some childhood cancers and leukaemias (Alexandrov et al., 2013; Shlien et al., 2015; Stratton, 2011).

A key focus of cancer genomics has been to classify somatic mutations according to whether or not they are under positive, neutral or negative selective pressure. Identifying the minority of mutations that are under positive selection and playing a causative role in oncogenesis (hereafter referred to as 'driver mutations') from mutations that do not confer a fitness advantage ('passenger mutations') is an ongoing and complex task (Lawrence et al., 2013; Martincorena et al., 2017; Stratton et al., 2009). The phenotypic features under positive selection in cancers have been conceptualised as the "hallmarks" of cancer and all, in essence, promote survival and/or growth (Hanahan and Weinberg, 2000, 2011). The most recent release of the Cancer Gene Census included 719 genes implicated in driving human cancers (Tate et al., 2019), although this list is constantly being amended and expanded to accommodate new genomic and functional evidence. The extent to which negative selection shapes somatic evolution in cancers and normal tissues is contentious, though at present most evidence suggests that positive selection plays a much more important role in governing clonal dynamics (Martincorena et al., 2017; Zapata et al., 2018).

### 1.1.2 Classifying cancer genes: tumour suppressors and oncogenes

Although often an oversimplification, it has proven conceptually useful to broadly classify cancer genes as either tumour suppressor genes or oncogenes. Tumour suppressor genes are implicated in oncogenesis through loss-of-function mutations (Stratton et al., 2009). Tumour suppressor genes frequently encode negative regulators of cell cycle progression (e.g., RB1, PTEN), suppressors of cell growth (e.g., NF1), pro-apoptotic signalling molecules (e.g., DAXX), proteins linking the DNA damage response to the cell cycle (e.g., ATM, TP53), cell-adhesion mediators (e.g., APC), DNA damage repair proteins (e.g., BRCA1) and epigenetic regulators (e.g., KDM6A, SETD2, DNMT3A, TET2) (Martincorena et al., 2017; Stratton, 2011). Many tumour suppressors, like the prototypical RB1 that gave rise to Knudson's 'two-hit' hypothesis (Knudson, 1971), function in a recessive manner (Stratton, 2011). However, for many tumour suppressors, haploinsufficiency alone promotes cancer development (e.g., TP53, RUNX1, PTEN, TET2, DNMT3A)(Döhner et al., 2015; Inoue and Fry, 2017). Many types of mutations can inactivate tumour suppressor genes, including truncating mutations (e.g., nonsense, frameshift, disruptive rearrangements, essential splice site mutations, gene deletions) as well as variants that disrupt key functional domains (Inoue and Fry, 2017).

Oncogenes are implicated in cancer through activating mutations and often encode growth factors or cytokine receptors (e.g., *EGFR, JAK2, KIT, PDGFRA*), their downstream signalling mediators (e.g., *PIK3CA, BRAF, NRAS, KRAS*) or negative regulators of tumour suppressors (e.g., *PPM1D*) (Nangalia et al., 2016; Ruark et al., 2013; Stratton, 2011). The types of mutations that result in activation or upregulation of oncogenes are diverse and include canonical hotspot missense mutations (e.g. *JAK2* V617F, *BRAF* V600E), chromosomal translocations or gene amplifications as well as deletions or truncating mutations that disrupt inhibitory regulatory domains (e.g., truncating mutations in *PPM1D* exon 6, intragenic *BRAF* deletions)(Forbes et al., 2011; Ruark et al., 2013; Stratton, 2011; Wegert et al., 2018).

It is increasingly recognised that many cancer genes, particularly those implicated in epigenetic regulation, do not fit tidily into this classification scheme. Many function as either tumour suppressors or oncogenes in different cancer types or even at different stages of the same cancer type (e.g., *EZH2*), reflecting the influence of cell-type, developmental context

and epistasis on the functional significance of many cancer driver mutations (Feinberg et al., 2016; Kim and Roberts, 2016; Shen et al., 2018; Van Vlierberghe and Ferrando, 2012).

Haematological cancers, and acute myeloid leukaemia in particular, are among the most extensively sequenced and genomically well-characterised of all cancer types (Medinger and Passweg, 2017; TCGA et al., 2013). Hence, the landscape of tumour suppressor and oncogenes relevant to these conditions has been well charted and the types of mutations that appear to be under positive selection in these genes is reasonably well defined, with concordance between many large studies (Bahr et al., 2018; Chen et al., 2018; Medinger and Passweg, 2017; Petti et al., 2018; TCGA et al., 2013; Tyner et al., 2018). The experiments described in this dissertation have taken a conservative approach to driver curation based on the criteria described in the largest relevant cancer genomics to date (Chapter 2).

### 1.1.3 Germline contributions to cancer risk

Studies of familial cancer predisposition and rare childhood cancer syndromes identified some of the first known cancer genes (Knudson, 1971; Maris, 2015). Germline variation plays an increasingly recognised role in cancer development, though its impact likely remains underestimated (Frick et al., 2018; Hermouet and Vilaine, 2011; Hinds et al., 2016; Huang et al., 2018; Loh et al., 2018; Parsons et al., 2016; Zhang et al., 2015). According to current estimates, overall approximately 1-2.7% of individuals without cancer have a putatively deleterious germline mutation in a cancer-associated gene, compared with 8.5 – 12.6% of cancer patients (Pritchard et al., 2016; Schrader et al., 2016; Zhang et al., 2015), though this rate appears considerably higher for some rare cancer types (Ballinger et al., 2016; Lu et al., 2015). Germline variants can influence cancer development by diverse mechanisms, including by directly driving clonal growth (Loh et al., 2018; Lu et al., 2015), increasing global mutation rate (Nik-Zainal, 2014; Shlien et al., 2015), increasing the likelihood of acquiring particular somatic driver events (Hermouet and Vilaine, 2011; Hinds et al., 2016; Loh et al., 2018) or altering carcinogen metabolism (Ding et al., 2010).

Studies of cancer predisposition syndromes have also demonstrated that the biological and clinical significance of germline and somatic variants in a given gene are often dramatically different (Maris, 2015; Maris and Knudson, 2015). For example, childhood myeloproliferative disease with germline mutations in *PTPN11* may follow an indolent, self-

resolving course, whereas somatic *PTPN11* mutations presage rapid progression and warrant prompt haematopoietic stem cell transplantation (HSCT)(Hasle, 2016). Furthermore, germline and somatic mutations in several cancer genes, notably *TP53* and *RB1*, drive a distinct spectrums of cancer types with predilections for different tissues and age groups (Maris and Knudson, 2015). The distinction between germline and somatic drivers is particularly relevant when interpreting the results of unmatched sequencing experiments such as those described in this thesis, and will be discussed further later on.

### 1.1.4 Mutational signatures

The entire complement of somatic mutations in a genome constitutes a record of the types of mutational processes operative during the lifetime of the organism. Certain patterns of mutation are characteristic of particular mutagenic exposures. For example, ultraviolet light-induced pyrimidine dimers are typically repaired by transcription-coupled nucleotide excision repair, which tends to result in C>T mutations on the untranscribed strand (Alexandrov et al., 2013). Substitutions, small insertions and deletions (indels) and complex structural events can be classified according to sequence context, thus allowing formal mathematical extraction of mutational signatures (Alexandrov et al., 2013; Li et al., 2017; Petljak et al., 2014).

Substitution mutational signatures have been most extensively studied. The six types of substitution mutation (C>A, C>G, C>T, T>A, T>C and T>G) can be classified into 96 subtypes based on their trinucleotide context. Various statistical approaches, predominantly based on non-negative matrix factorisation, can discern distinct patterns of co-occurrence of substitution types (Alexandrov et al., 2018; Alexandrov et al., 2013). At present, only a minority of putative mutational signatures have a known cause (Alexandrov et al., 2018; Alexandrov et al., 2013). Nevertheless, mutational signature analysis has yielded compelling insights into the causes and epidemiology of several cancer types, and are increasingly being used clinically to guide diagnosis, prognostication and therapeutic strategy (Behjati et al., 2016; Hoang et al., 2013; Ma et al., 2018; Petljak and Alexandrov, 2016; Poon et al., 2015).

All cancers harbour a significant number of mutations attributed to ageing-associated single base substitution signatures 1 (SBS1) and 5 (SBS5) (Alexandrov et al., 2018; Alexandrov et al., 2013). SBS1 is dominated by C>T mutations attributed to spontaneous deamination of

5-methylcytosine, whilst SBS5 is of unknown aetiology (Alexandrov et al., 2018; Alexandrov et al., 2013). Myeloid malignancies are characterised by very low mutation burdens, similar to those observed in normal haematopoietic stem cells from age-matched individuals (Welch et al., 2012). Consistent with this finding, most of these mutations are attributable to SBS1 and SBS5 (Alexandrov et al., 2018; Alexandrov et al., 2013). A significant proportion of AML demonstrate evidence of SBS18, attributed to reactive oxygen species-mediated DNA damage (Alexandrov et al., 2018). A small proportion of myelodysplasia and myeloproliferative disease specimens harbour mutations attributable to SBS32, a signature thought to be caused by azathioprine treatment (Alexandrov et al., 2018). Although lymphoid neoplasms are also generally dominated by age-related SBS1 and SBS5 (Alexandrov et al., 2013), they tend to have higher mutation burdens than myeloid cancers and a more complex mutational signature complement, with some specimens harbouring evidence of defective DNA repair mechanisms or APOBEC activity (Alexandrov et al., 2018; Alexandrov et al., 2013).

### 1.2 Cancer is an evolutionary process

The notion that cancer development is a clonal (originating from a single ancestral cell) evolutionary process can be traced back to Boveri and was further advanced in the 1950s based on histological observation of the natural history of precancerous lesions and their response to extrinsic irritants (Denoix, 1954; Foulds, 1958). Following the acceptance of the mutational theory of cancer, Peter Nowell and John Cairns conceptualised the modern understanding of cancer evolution in their seminal 1970s reviews (Cairns, 1975; Nowell, 1976).

"The acquired genetic instability and associated selection process, most readily recognized cytogenetically, results in advanced human malignancies being highly individual karyotypically and biologically. Hence, each patient's cancer may require individual specific therapy, and even this may be thwarted by emergence of a genetically variant subline resistant to the treatment. More research should be directed toward understanding and controlling the evolutionary process in tumors before it reaches the late stage usually seen in clinical cancer."

- Peter Nowell, 1976 (Nowell, 1976)

Cairns spoke more explicitly in terms of natural selection acting on inevitable mutations arising in stem cells throughout the lifespan of an organism:

"Survival of the rapidly renewing tissues of long-lived animals like man requires that they be protected against the natural selection of fitter variant cells (that is, the spontaneous appearance of cancer)."

- Cairns 1975 (Cairns, 1975)

The ability to sequence many specimens of the same tumour type demonstrated remarkable genetic diversity within the same histopathological diagnosis (Yates and Campbell, 2012). Phylogenetic inference, multi-region tumour sequencing and single cell methods revealed striking intra-tumour heterogeneity (Anderson et al., 2011; Gerlinger et al., 2012; Greaves, 2015; Navin et al., 2011). These observations established that the evolutionary routes to cancer are diverse and that malignant clones continue to acquire mutations, compete and evolve (Ding et al., 2012; Greaves and Maley, 2012; Nik-Zainal et al., 2012). It became possible to construct phylogenetic trees at unprecedented resolution. Consistent features of these trees illustrate key principles of cancer pathogenesis. At their base, all cancer phylogenetic trees have the ancestral cell with the initial complement of driver mutations, along with all other mutations previously acquired by that cell and captured as the clone expanded (Yates and Campbell, 2012). Each cell within the expanded clone continues to acquire mutations, which are subclonal. With a few exceptions (e.g., chromothripsis causing multiple simultaneous driver mutations (Stephens et al., 2011)), in almost all cases cancer phylogenies support the gradual, multi-step model of carcinogenesis (Greaves, 2015; Yates and Campbell, 2012). Tumour cells continually diversify through acquisition of additional mutations and clonal architecture may follow branching, parallel or convergent evolutionary trajectories (Greaves, 2015; Yates and Campbell, 2012). The relative influence of mutation-induced cell-intrinsic growth advantage, selective pressures and genetic drift in cancer evolution remains contentious (Martincorena and Campbell, 2015; Martincorena et al., 2017; Sun et al., 2017; Zink et al., 2017). Phylogenetic trees constructed from multi-region or serial sampling have yielded insights into some of the selection pressures implicated in cancer clonal competition, discussed briefly in the next section.

### 1.2.1 Selection pressures shaping cancer evolution

#### 1.2.1.1 The tumour microenvironment

The idea that the tumour microenvironment influences cancer development was first put forward in the late 19<sup>th</sup> century by Ernst Fuchs and Stephen Paget based on detailed anatomical studies of tumour metastases (Fuchs, 1882; Paget, 1889). Paget likened tumour cells to 'seeds' that required a favourable microenvironment, or 'soil' to survive and grow (Paget, 1889). The factors underpinning the predilection of metastases for certain organs are still incompletely understood (Hunter et al., 2018). However, several studies that used multiregion sampling or tumour organoids have elucidated the phylogenetic relationships between primary tumour lesions and metastases and provided insight into the interplay between genetic diversification and organ-specific selection pressures (Altorki et al., 2019; Campbell et al., 2010; Gundem et al., 2015; Hunter et al., 2018; Makohon-Moore and Iacobuzio-Donahue, 2016; Roerink et al., 2018; Yachida et al., 2010). It is now clear that interactions between cancer cells and tissue microenvironment are relevant far beyond metastasis, exerting selective pressures important at all stages of solid and haematological cancer development (Medyouf, 2017; Scott and Gascoyne, 2014; Yates and Campbell, 2012; Yokoyama et al., 2019).

#### 1.2.1.2 Cancer therapies

Anticancer therapy is often one of the most potent selective pressures governing cancer evolution (Yates and Campbell, 2012). Resistance mechanisms are diverse (Holohan et al., 2013), however, as sequencing technologies become more sensitive, it is increasingly clear that resistance mutations to both conventional cytotoxic agents and targeted therapies frequently predate treatment at extremely low subclonal levels (Karoulia et al., 2017; Kennedy et al., 2014; Schmitt et al., 2016; Wong et al., 2015a; Wong et al., 2015b). As presciently anticipated by Nowell (Nowell, 1976), the extensive genetic diversity present in fully fledged cancers represents a formidable arsenal of potential adaptive strategies and has greatly undermined targeted therapy efforts (Holohan et al., 2013).

Scrutiny of cancer genomes has yielded profound insight into the genetic drivers and evolutionary dynamics of most human cancer types. However, it is now evident that this work

did not adequately capture the somatic genetic diversity and selective pressures shaping the pre-cancerous phases of oncogenesis. Recent studies of somatic evolution in morphologically normal tissues have yielded compelling biological insights into normal ageing and its relationship with cancer development. The next section will give a broad overview of these advances with a focus on the haematopoietic system.

## 2. Somatic evolution in normal ageing tissues and its relationship to cancer

"Cancer is a chronic disease with a long history extending back for many years before clinical signs are evident."

- Leslie Foulds, 1958 (Foulds, 1958)

"...the whole body is seeded with tumor cells whose evolutionary potential is revealed at unpredictable times thereafter."

Foulds's summary of a hypothesis proposed by Pierre Denoix in his 1954 paper 'De la diversité de certains cancers' (Denoix, 1954; Foulds, 1958)

The molecular basis of multi-step carcinogenesis was meticulously dissected in childhood leukaemia and colon cancer in the 1980s and 1990s and gave preliminary insights into the ambiguous boundary between normal tissue, pre-cancer and fully-fledged malignancy (Fearon and Vogelstein, 1990; Greaves et al., 2003). Studies of monozygotic twins concordant for leukaemia demonstrated that the initiating event, typically a fusion gene, arises in a single cell *in utero*, which transfers to the second twin via a monochorionic placenta (Greaves and Wiemels, 2003). For most childhood leukaemia, the latency to disease onset suggested that the initiating translocation (most commonly the *TEL–AML1* fusion gene), requires a second hit to trigger malignant transformation (Greaves and Wiemels, 2003). In support of this hypothesis, several studies screened healthy newborns for leukaemogenic fusions and found their prevalence to be considerably higher than the cumulative incidence of childhood leukaemia (Greaves et al., 2011; Lausten-Thomsen et al., 2011; Mori et al., 2002; Zuna et al., 2011). Furthermore, not all twins concordant for the initiating event are concordant for

leukaemia (Bateman et al., 2015). Collectively, these findings provided genetic evidence to support Foulds and Denoix's hypothesis that pre-cancer is considerably more common than cancer and that malignant progression is not readily predictable. These conclusions were also supported by the natural history and molecular features of the adenoma-carcinoma sequence in the colon (Fearon and Vogelstein, 1990).

The advent of sensitive sequencing methods has recently revealed that potentially premalignant clonal expansions are remarkably common in many normal ageing tissues (Bowman et al., 2018; Martincorena et al., 2018; Martincorena et al., 2015; Moore et al., 2018; Salk et al., 2018; Suda et al., 2018; Yizhak et al., 2018; Yokoyama et al., 2019). This phenomenon has been most extensively explored in skin (Martincorena et al., 2015), oesophagus (Martincorena et al., 2018; Yokoyama et al., 2019), endometrium (Moore et al., 2018; Salk et al., 2018; Suda et al., 2018; Yokoyama et al., 2019), endometrium (Moore et al., 2018; Salk et al., 2018; Suda et al., 2018) and blood (Bowman et al., 2018), though preliminary evidence from bulk RNA sequencing of diverse normal tissues suggests that clonal expansions harbouring canonical cancer driver mutations may be ubiquitous in most organs (Yizhak et al., 2018).

Several common themes are beginning to emerge from these findings. Firstly, there is generally a clear association between age and prevalence of readily detectable clonal expansions, with that latter apparently trending towards inevitability by midlife in many tissues (Martincorena et al., 2018; Martincorena et al., 2015; Suda et al., 2018; Young et al., 2016). However, it is not yet clear to what extent age-related mutation acquisition is a ratelimiting step in clonal expansion. Potent cancer driver mutations, including hotspot TP53 mutations, may be dated to early infancy or childhood in several tissues and may never contribute to cancer even in high risk individuals (Greaves et al., 2011; Moore et al., 2018; Yokoyama et al., 2019). It is increasingly apparent that selective pressures, some correlated with ageing, impact the fitness advantage of particular mutations and hence modulate clonal dynamics (Hsu et al., 2018; McKerrell and Vassiliou, 2015; Murai et al., 2018; Wong et al., 2015b; Yokoyama et al., 2019). For example, exposure to smoking and alcohol accelerates clonal growth in normal oesophagus (Yokoyama et al., 2019) and ultraviolet radiation exposure influences the fitness advantage of epidermal TP53 mutations (Murai et al., 2018). The proliferation of clonal expansions with age may reflect both mutation accrual and ageingassociated changes in tissue microenvironments that confer increasing fitness advantage on oncogenic mutations (Armitage and Doll, 1954; Nordling, 1953; Rozhok and DeGregori, 2015).

A second observation that has been made in several tissue types is that the mutational spectrum of age-associated clonal expansions may differ from that seen in cancer (Busque et al., 2018; Martincorena and Campbell, 2015; Martincorena et al., 2018; Xie et al., 2014; Yokoyama et al., 2019). For example, putative driver mutations in *NOTCH1* are more frequently seen in clonal expansions in histologically normal skin and oesophagus than in cancers arising from these tissues (Martincorena et al., 2018; Martincorena et al., 2015; Yokoyama et al., 2019). Similarly, activating mutations in *PPM1D*, which encodes a negative regulator of TP53, are more frequent in normal blood and oesophagus than in malignancy (Bowman et al., 2018; Xie et al., 2014; Yokoyama et al., 2019). Most relevant experiments have employed targeted sequencing of known cancer-associated genes, thus hindering an unbiased comparison between the mutational landscape of cancer and normal ageing. Equally, the ubiquity of certain mutations in normal tissues, and by extension their recurrence in the trunks of tumour phylogenetic trees, could lead to overestimates of their importance in cancer pathogenesis (Ciccarelli, 2019).

How mutations and selective pressures interact to determine the likelihood of malignant transformation is an important biological question with compelling clinical implications. As predicted by Cairns (Cairns, 1975), emerging evidence suggests that some epithelial tissues have evolved mechanisms for restraining growth of clones harbouring oncogenic mutations (Murai et al., 2018; Ying et al., 2018). Senescence and immune surveillance are also involved in policing mutated clones (Collado et al., 2005; Schreiber et al., 2011). However, understanding of the factors governing physiological cell competition and tissue homeostasis in humans and their relationship with carcinogenesis remains very limited. A significant obstacle to studying these questions in most organs is the inability to obtain representative tissue samples. The haematopoietic system has proven a privileged setting in which to explore somatic evolution and its relationship with ageing and ageing-associated pathologies (Bowman et al., 2018; Geiger et al., 2013; Latchney and Calvi, 2017; Lee-Six et al., 2018). The next section will summarise current understanding of clonal haematopoiesis and its clinical relevance.

### 3. Clonal haematopoiesis

### 3.1 Prevalence and mutational landscape of clonal haematopoiesis

Blood has one of the highest turn-over rates of any tissue, necessitating the production of trillions of cells per day by a population of haematopoietic stem cells (HSCs) estimated to number between 50,000 and 200,000 (Carrelha et al., 2018; Doulatov et al., 2012; Lee-Six et al., 2018). Replicative mutagenesis and other sources of genotoxic stress cause HSCs to accumulate DNA damage with age, with an estimated 14 mutations accumulating per cell per year (Flach et al., 2014; Osorio et al., 2018; Rossi et al., 2007; Welch et al., 2012; Yahata et al., 2011). Clonal haematopoiesis (CH) refers to the disproportionate expansion of one somatically mutated HSC clone relative to others. Many reports have now identified this phenomenon in a significant proportion of individuals without a haematological cancer (Acuna-Hidalgo et al., 2017; Akbari et al., 2014; Artomov et al., 2017; Bonnefond et al., 2013; Buscarlet et al., 2017; Busque et al., 1996; Busque et al., 2012; Coombs et al., 2017; Forsberg et al., 2012; Frick et al., 2018; Genovese et al., 2014; Gibson et al., 2017; Gillis et al., 2017; Jacobs et al., 2012; Jaiswal et al., 2014; Jaiswal et al., 2017; Laurie et al., 2012; Loftfield et al., 2018b; Loh et al., 2018; Machiela et al., 2015; McKerrell et al., 2015; Rodriguez-Santiago et al., 2010; Savola et al., 2017; Schick et al., 2013; Takahashi et al., 2017; Thompson et al., 2019; Vattathil and Scheet, 2016; Xie et al., 2014; Young et al., 2016; Zhou et al., 2016; Zink et al., 2017). Clonal haematopoiesis was first recognised in the 1990s when Busque and colleagues demonstrated that ageing was associated with increasingly skewed X-inactivation in blood cells (Busque et al., 1996). Busque et al. applied a PCR-based X-inactivation clonality assay to peripheral blood samples from a cohort of 295 healthy females spanning a broad age range (Busque et al., 1996). Using stringent criteria for skewing (allele ratios >= 10:1), this approach identified imbalanced X-inactivation in 22.7%, 4.5% and 1.9% of women aged >=60 years, 28-32 years and <1 month, respectively (Busque et al., 1996).

The advent of molecular karyotyping using SNP arrays demonstrated that a significant proportion of the general population harbours clonal, somatic chromosomal abnormalities in blood cells (Artomov et al., 2017; Bonnefond et al., 2013; Forsberg et al., 2012; Jacobs et al., 2012; Laurie et al., 2012; Loftfield et al., 2018a; Loh et al., 2018; Machiela et al., 2015;

Rodriguez-Santiago et al., 2010; Schick et al., 2013; Vattathil and Scheet, 2016; Zhou et al., 2016). These studies identified a clear correlation between age and frequency of clonal mosaic aneuploidy or copy-neutral loss of heterozygosity (LOH) events, with prevalence varying from <0.5% in individuals under age 50 years to 1.9-3.4% in persons aged >60 (Forsberg et al., 2012; Jacobs et al., 2012; Laurie et al., 2012). The most recurrent abnormalities included del(13q), trisomy 8, del(20q), del(5q) and del(7q), chromosomal changes characteristic of haematological malignancies (Forsberg et al., 2012; Jacobs et al., 2012; Laurie et al., 2012; Laurie et al., 2012). Mosaic chromosomal changes were associated with a five- to tenfold higher risk of subsequently developing haematological cancers (Jacobs et al., 2012; Laurie et al., 2012; Schick et al., 2013). Longitudinal tracking of clonal chromosomal abnormalities has yielded variable results, with one study suggesting that aberrant clones may become undetectable over time (Forsberg et al., 2017), while another series of 47 individuals sampled several years apart found that most clones expanded with age (Machiela et al., 2015).

Next-generation sequencing technologies enabled higher resolution scrutiny of the genetic changes driving clonal haematopoiesis. Sequencing of healthy women with skewed X-inactivation identified mutations in the epigenetic regulator TET2 in 5.5% (10/182 individuals) (Busque et al., 2012). In 2014, three large exome sequencing studies identified leukaemia-associated point mutations in the blood of >2% of individuals unselected for haematological phenotypes (Genovese et al., 2014; Jaiswal et al., 2014; Xie et al., 2014). All three studies reported a steep rise in CH prevalence with age, ranging from <1% under age 50 years to around 10% in individuals over age 70 (Genovese et al., 2014; Jaiswal et al., 2014; Xie et al., 2014). The majority of candidate driver mutations occurred in TET2, DNMT3A and ASXL1, epigenetic regulators commonly mutated in myeloid malignancies (Arber et al., 2016; Genovese et al., 2014; Jaiswal et al., 2014; Xie et al., 2014). Jaiswal et al. interrogated a predefined set of 160 cancer-associated genes, whereas Genovese et al. and Xie et al. screened for CH in an unbiased manner on the basis of unusual allele frequencies (Genovese et al., 2014; Xie et al., 2014). The latter approach identified a broader spectrum of putative CH drivers, most notably a remarkably high frequency of mutations in PPM1D, a negative regulator of TP53 that is infrequently mutated in haematological or solid cancers (Genovese et al., 2014; Ruark et al., 2013; Xie et al., 2014). Other recurrently mutated genes included JAK2, TP53, spliceosome genes (SF3B1, SRSF2 and U2AF1), CBL, BCORL1, ATM, MYD88 and GNAS (Genovese et al., 2014; Jaiswal et al., 2014; Xie et al., 2014).

Later studies of CH in the general population used more sensitive targeted sequencing approaches and demonstrated that CH prevalence increases dramatically with assay sensitivity (Acuna-Hidalgo et al., 2017; Buscarlet et al., 2017; McKerrell et al., 2015; Young et al., 2016; Zink et al., 2017). Young et al. used molecular barcoding to enable detection of mutations at a variant allele frequency (VAF) as low as 0.0003 and found CH to be ubiquitous in otherwise healthy individuals aged >50 years (Young et al., 2016). The genes recurrently implicated in CH were broadly consistent across these studies. However, whilst the prevalence of mutations in all genes increased with age, certain mutations were found to be particularly enriched in older individuals (McKerrell et al., 2015). In particular, spliceosome gene mutations were seen almost exclusively in individuals aged >70 (Acuna-Hidalgo et al., 2017; McKerrell et al., 2015), whereas the frequency of mutations in *DNMT3A* and *JAK2* increased more linearly with age (Acuna-Hidalgo et al., 2017; Buscarlet et al., 2017; McKerrell et al., 2015). A less dramatic age-dependence has been observed for *TET2* mutations (Buscarlet et al., 2017).

Ageing is just one example of how the mutational landscape of CH varies according to clinical context. CH is extremely common in aplastic anaemia patients and displays a distinct spectrum of somatic mutations (Stanley et al., 2017; Yoshizato et al., 2015). Similarly, CH enriched in *TP53* and *PPM1D* mutations is prevalent in individuals who have been exposed to chemo- and/or radiotherapy (Coombs et al., 2017; Gibson et al., 2017; Gillis et al., 2017; Takahashi et al., 2017). Further discussion of the interplay between somatic mutations and dynamic selection pressures is discussed in section 3.4.

Zink et al. conducted a broader, though less sensitive, screen for CH by interrogating 11,262 whole genomes (median coverage 35x) for unusual SNV allele frequency distribution, similar to the variant calling strategies applied by Xie et al. and Genovese et al. (Genovese et al., 2014; Xie et al., 2014; Zink et al., 2017). Consistent with previous data and predictions, CH was almost universally detectable in individuals >85 years of age (McKerrell et al., 2015; Young et al., 2016; Zink et al., 2017). The overall prevalence of CH (identified on the basis of having > 20 putative mosaic point mutations) was 12.5%, higher than that observed in previous studies (Zink et al., 2017). Presumptive driver mutations were most frequent in *DNMT3A*, *TET2*, *ASXL1* and *PPM1D* (Zink et al., 2017). However, candidate driver mutations were only identified in a minority of individuals with CH (Zink et al., 2017). The authors suggest genetic drift as a likely explanation for this result. However, numerical and structural

chromosomal changes were not systematically identified and may account for a significant proportion of the CH cases without an apparent point mutation driver (Artomov et al., 2017; Bonnefond et al., 2013; Forsberg et al., 2012; Jacobs et al., 2012; Laurie et al., 2012; Loftfield et al., 2018a; Loftfield et al., 2018b; Loh et al., 2018; Machiela et al., 2015; Rodriguez-Santiago et al., 2010; Schick et al., 2013; Vattathil and Scheet, 2016; Zhou et al., 2016). Contiguous gene deletions and rearrangements are common initiating driver events in many haematological cancers. It is possible that structural variants under positive selection underpinned a significant proportion of the CH cases attributed to drift. It is also conceivable that there is only partial overlap between cancer drivers and the mutations that are under positive selection in somatic evolution in normal ageing blood. The preponderance of *PPM1D* and *NOTCH1* mutations in clonal expansions in normal tissues compared to cancers may support this hypothesis (Bowman et al., 2018; Martincorena et al., 2018; Martincorena et al., 2015; Yokoyama et al., 2019). Zink et al. did perform an unbiased search for novel driver genes, but did not identify many candidates (Zink et al., 2017).

Mutations in certain common myeloid cancer genes, notably *FLT3* and *NPM1*, were consistently absent in even the most sensitive CH screens, supporting their role as late cooperating/transforming mutations rather than initiating events (Acuna-Hidalgo et al., 2017; Genovese et al., 2014; Jaiswal et al., 2014; McKerrell et al., 2015; Xie et al., 2014).

### 3.2 Germline influences on CH

Extensive evidence demonstrates that germline variation is an important determinant of clonal haematopoiesis risk and clinical outcome (Buscarlet et al., 2017; Frick et al., 2018; Hinds et al., 2016; Jones et al., 2009; Kilpivaara et al., 2009; Koren et al., 2014; Loftfield et al., 2018a; Loh et al., 2018; Olcaydu et al., 2009; Thompson et al., 2019; Wright et al., 2017; Zhou et al., 2016; Zink et al., 2017). Heritable polymorphisms can influence CH development by increasing susceptibility to somatic mutagenesis (Hinds et al., 2016; Jones et al., 2009; Kilpivaara et al., 2009; Koren et al., 2014; Loh et al., 2018; Olcaydu et al., 2009; Zhou et al., 2016) or by modulating positive or negative clonal selection (Hinds et al., 2016; Loh et al., 2018). For example, the *JAK2* 46/1 haplotype is a well-recognised risk factor for acquiring *JAK2* V617F-positive CH and progressing to a myeloid neoplasm (Jones et al., 2009; Kilpivaara et al., 2009; Olcaydu et al., 2009). Polymorphisms in several other genes, including *TERT*, *TET2*, *ATM* and *CHEK2*, are also associated with *JAK2* V617-driven myeloproliferative neoplasms and hence perhaps also antecedent clonal haematopoiesis (Hinds et al., 2016). Over 150 loci have now been strongly linked to overall CH risk, or risk of particular chromosomal losses or likelihood of specific LOH events amplifying the selective advantage conferred by inherited or somatic driver events (Loh et al., 2018; Thompson et al., 2019; Wright et al., 2017; Zink et al., 2017). Additionally, several germline polymorphisms have been shown to impact leucocyte DNA replication timing, and by consequence, the susceptibility of nearby sequence to somatic mutagenesis (Koren et al., 2014). In a recent large survey of mosaic chromosomal changes in peripheral blood, Loh et al. identified several highly penetrant heritable variants associated with increasing mutability of nearby DNA sequence, including in the myeloid oncogene *MPL* (Loh et al., 2018). Several of the variants were also subject to clonal selection and impacted risk of progression to haematological cancer (Loh et al., 2018).

A main emerging message from these studies is the increasingly blurry distinction between heritable and somatically acquired determinants of clonal haematopoiesis development and natural history. Furthermore, the influence of germline variation on CH incidence and outcome probably remains underestimated. Several studies report familial or ethnic clustering of CH suggesting yet to be discovered heritable risk factors (Buscarlet et al., 2017; Frick et al., 2018; Loftfield et al., 2018a). Moreover, a large number of uncommon germline variants have emerged as important determinants of haematological phenotypes in the general population, and it is plausible that these exert epistatic, lineage biased effects on CH evolution (Astle et al., 2016).

### 3.3 Clinical significance of clonal haematopoiesis

### 3.3.1 Impact of clonal haematopoiesis on blood indices

Mutations common in CH are implicated in ineffective haematopoiesis, impaired differentiation and cytopenias when they occur in individuals with MDS or AML (Papaemmanuil et al., 2016; Steensma et al., 2015). However, CH harbouring putative driver mutations (CH-PD) is not generally associated with any abnormalities in blood cell counts (Buscarlet et al., 2017; Jaiswal et al., 2014; McKerrell et al., 2015). Jaiswal et al. analysed blood indices data available for 3107 individuals, 4.5% of whom had CH-PD and found no significant differences in haemoglobin levels, platelet counts or white-cell differential counts (Jaiswal et al.

al., 2014). The only blood index that differed significantly was red cell distribution width (RDW), which was higher in individuals with CH-PD and correlated with mutation VAF (Jaiswal et al., 2014). Moreover, although the prevalence of a single cytopenia was not influenced by CH status, individuals with multiple cytopenias were more likely to have CH (odds ratio 3.0)(Jaiswal et al., 2014).

While CH may rarely cause haematological indices to deviate to a clinically significant degree, Loh et al. recently demonstrated that some acquired mutations correlate with trends in blood counts, though generally within the reference range (Loh et al., 2018). Their findings suggest lineage-specific clonal selection pressures mirroring those observed in blood cancers (Loh et al., 2018). For example, chromosome 9p LOH (encompassing *JAK2*) and trisomy 12 (highly recurrent in CLL) were associated with higher granulocyte and lymphocyte counts, respectively (Loh et al., 2018).

### 3.3.2 Clonal haematopoiesis and haematological malignancy

Numerous studies have reported a clear association between CH in haematologically normal individuals and risk of developing a haematological malignancy (Coombs et al., 2017; Genovese et al., 2014; Gibson et al., 2017; Gillis et al., 2017; Greaves and Wiemels, 2003; Jacobs et al., 2012; Jaiswal et al., 2014; Laurie et al., 2012; Loh et al., 2018; Schick et al., 2013; Takahashi et al., 2017; Zink et al., 2017). This is perhaps unsurprising given that the multi-step model of cancer implies a premalignant phase in cancer evolution (Yates and Campbell, 2012). Furthermore, several studies of haematological cancer evolution have demonstrated that myeloid malignancies evolve from a population of preleukaemic stem cells harbouring initiating driver mutations, and that such preleukaemic HSCs can persist during long-term remission and serve as a reservoir for relapse (Greaves et al., 2003; Jan et al., 2012; Shlush et al., 2017; Shlush et al., 2014). Similar observations hold true for the commonest lymphoid malignancies (Landgren et al., 2009; Ojha et al., 2014; Rawstron et al., 2008). However, the prevalence of preleukaemic HSC clones and the rate and determinants of progression to leukaemia remain unknown. The studies cited above demonstrate that the rate of CH in the general population, and in particular CH harbouring putative driver mutations (CH-PD), vastly exceeds the cumulative incidence of blood cancers (Bowman et al., 2018). Given the variation in cohort characteristics, follow-up time and CH detection sensitivity, it is unsurprising that

the strength of the association reported between CH and haematological cancer risk has varied between studies (Coombs et al., 2017; Genovese et al., 2014; Gibson et al., 2017; Gillis et al., 2017; Greaves and Wiemels, 2003; Jacobs et al., 2012; Jaiswal et al., 2014; Laurie et al., 2012; Loh et al., 2018; Schick et al., 2013; Takahashi et al., 2017; Zink et al., 2017). Notably, Zink et al. and Genovese et al. found that the risk of malignant progression was the same regardless of whether a point mutation driver (versus no driver) was identified (Genovese et al., 2014; Zink et al., 2017). However, as discussed previously, it is possible that CH without such mutations may reflect unsought structural driver events.

Most studies of cohorts unselected for cancer or haematological phenotype have reported an approximately ten-fold increased risk of blood cancer among individuals with CH (Genovese et al., 2014; Jaiswal et al., 2014). However, this still reflects a low absolute risk for malignant progression. Jaiswal et al. found that individuals with CH-PD (assay sensitivity limit 3.5% and 7.0% for SNVs and indels, respectively) had a 4% risk of blood cancer diagnoses over a median follow-up period of 7.9 years (Jaiswal et al., 2014). This translates into an overall annual progression rate of 0.5%, rising to 1% per year among individuals with driver mutations present at VAF > 0.1 (Jaiswal et al., 2014). Similarly, Genovese et al. reported similar findings, and in addition were able to demonstrate a clonal relationship between CH and blood cancer in the two individuals for whom diagnostic bone marrow specimens were available (Genovese et al., 2014). In both of these cases, the interval between blood sampling and cancer diagnosis was modest (2 and 34 months) (Genovese et al., 2014). Both Jaiswal et al. and Genovese et al. found that only a minority of the blood cancers arising during follow-up were diagnosed in individuals with antecedent CH: 5/16 (31%) and 13/31 (42%), respectively (Genovese et al., 2014; Jaiswal et al., 2014). This finding, in conjunction with the ubiquity of CH relative to blood cancer incidence, raises clinically and biologically compelling questions about the natural history of haematological cancers and the pathophysiological relevance of CH.

From a clinical perspective, it is sobering that the main cause of mortality from many of the commonest adult haematological cancers remains treatment resistance, despite a growing arsenal of novel targeted therapies (Abdi et al., 2013; Döhner et al., 2015; Woyach and Johnson, 2015). There is hence a compelling rationale for identifying and treating a genomically simpler antecedent of the disease. In this context, reduction of clonal size rather than complete clonal extinction may be sufficient to significantly reduce the risk of malignant progression. Such an approach has proven very effective in CML, which has been transformed into a chronic condition by targeted therapy, whereas CML blast crisis remains very challenging to treat (Gore et al., 2018; Hunger, 2017; O'Brien et al., 2003). The eventual feasibility of earlier detection and intervention for nascent blood cancers will invariably be hampered by the high prevalence of benign CH, given the relative rarity of the former. However, CH is associated with and may play a causal role in several much commoner conditions, which may broaden indications for its use as a clinical biomarker or a therapeutic target for non-haematological pathologies. The broader clinical significance of CH is summarised in the following sections.

### 3.3.3 Clonal haematopoiesis and non-haematological cancers

Clonal haematopoiesis has been associated with both a higher risk of solid cancers (Akbari et al., 2014; Artomov et al., 2017; Bowman et al., 2018; Ruark et al., 2013; Thompson et al., 2019) and with higher mortality among solid tumour and lymphoma patients (Coombs et al., 2017; Gibson et al., 2017). However, it is challenging to study the relationship between CH and solid cancer risk given that cancer treatments dramatically increase CH incidence and many study participants were not chemotherapy/radiotherapy naïve (Akbari et al., 2014; Artomov et al., 2017; Ruark et al., 2013). It is also possible that germline cancer predisposition is a confounding risk factor for both CH and overall cancer risk.

The association between CH and mortality among cancer patients has been consistently observed across diverse cohorts (Coombs et al., 2017; Gibson et al., 2017; Gillis et al., 2017), though may also be subject to some confounding factors, e.g., germline cancer predisposition. Furthermore, cancer treatment intensity correlates with CH risk (Coombs et al., 2017; Gibson et al., 2017; Gillis et al., 2017; Takahashi et al., 2017) and toxicity-related mortality, and may be higher in individuals with more advanced malignancies. These potential confounders are hard to control for across retrospective cohorts comprising individuals with diverse solid cancer types.

Any mechanistic link between CH and solid tumour pathogenesis remains speculative. It is possible that clonal haematopoiesis may promote solid tumour growth by fostering hospitable tissue microenvironments (Bowman et al., 2018). The term 'tumour-associated macrophage' (TAM) encompasses phenotypically diverse cells that can play both oncogenic or tumour-suppressive roles (Mantovani et al., 2017). It is intriguing that the cytokine profile of the *TET2*-mutated macrophages implicated in atherosclerosis (Jaiswal et al., 2017) shares key features with that seen in oncogenic TAMs (Storr et al., 2017; Wang et al., 2018).

### 3.3.4 Clonal haematopoiesis and non-malignant conditions

Several studies have found that clonal haematopoiesis is associated with a higher overall mortality rate that is only partially due to cancer deaths (Coombs et al., 2017; Genovese et al., 2014; Gibson et al., 2017; Jaiswal et al., 2014; Loftfield et al., 2018a; Loh et al., 2018; Zink et al., 2017). The majority of excess mortality has been attributed to cardiovascular disease (CVD), ischaemic stroke and diabetes (Bonnefond et al., 2013; Coombs et al., 2017; Fuster et al., 2017; Genovese et al., 2014; Gibson et al., 2017; Jaiswal et al., 2014; Jaiswal et al., 2017; Loftfield et al., 2018a; Sano et al., 2018a; Sano et al., 2018b). Preliminary evidence also links CH with rarer inflammatory conditions, such as rheumatoid arthritis (Savola et al., 2017).

It has long been recognised that known cardiovascular risk factors - namely hypertension, lipid profile, smoking and obesity - only partially account for atherosclerotic diseases burden and that other poorly characterised pro-inflammatory processes likely contribute (Ross, 1999). A large prospective case-control study recently confirmed the association between CH and risk of coronary heart disease, independent of age and other known risk factors (Jaiswal et al., 2017). This association held regardless of whether CH harboured mutations in DNMT3A, TET2, JAK2 or ASXL1 (Jaiswal et al., 2017). Individuals with CH had significantly more coronary artery calcification, a surrogate marker of atherosclerosis severity (Jaiswal et al., 2017). Moreover, compelling evidence now supports a causal role for CH in atherosclerosis and cardiometabolic disease (Fuster et al., 2017; Jaiswal et al., 2017; Sano et al., 2018a). Jaiswal et al. engrafted TET2-mutated cells into hypercholesterolaemiaprone mice and found that the TET2-deficient animals developed accelerated atherosclerotic disease (Jaiswal et al., 2017). Transcriptional profiling of TET2-mutant macrophages from arterial plaques revealed increased expression of pro-inflammatory mediators implicated in atherosclerosis, including CXCL1, CXCL2, IL-1b and IL-6 (Jaiswal et al., 2017). These findings were corroborated by a similar mouse model study by Fuster et al., which further demonstrated that inhibition of IL-1b secretion was more effective in slowing atherosclerosis in mice engrafted with TET2-deficient bone marrow than in controls (Fuster et al., 2017). Sano

et al. found that *TET2*-mutant CH increases IL-1b levels, accelerates cardiac failure in mice, and can be mitigated with anti-inflammatory therapy targeting IL-1b production (Sano et al., 2018a). A recent randomised, double blind trial of canakinumab, a therapeutic monoclonal antibody targeting IL-1b, reduced cardiovascular morbidity and mortality in humans independent of lipid profile (Ridker et al., 2017). Trial participants were not screened for CH, so it remains to be investigated whether CH could serve as a useful human biomarker or therapeutic target in its own right.

Myeloproliferative diseases are associated with increased cardiovascular morbidity and mortality mediated by multiple mechanisms (Deininger et al., 2017). In a retrospective nested case-control study including 10,000 individuals without a known myeloid neoplasm, *JAK2*-mutant CH was associated with an increased thrombosis risk (Wolach et al., 2018). This association appears at least partially attributable to a mutant *JAK2*-mediated increase in prothrombotic neutrophil extracellular trap (NET) formation (Wolach et al., 2018). In a mouse model of *JAK2*-mutant CH, NET formation and thrombosis was reduced upon administration of ruxolitinib, a *JAK2* inhibitor (Wolach et al., 2018).

It is not yet known whether CH with mutations in other genes plays a causative role in atherosclerosis, though the strong association between *DNMT3A*- and *ASXL1*-mutant CH and CVD (Jaiswal et al., 2017) warrants further investigation. It is intriguing that atherogenic haemodynamic stress appears to reprogram endothelial gene expression via a DNA methyl-transferase (DNMT)-dependent mechanism and that DNMT inhibition with siRNA or decitabine can reduce vascular endothelial inflammation and atherosclerosis formation in multiple mouse models (Dunn et al., 2014; Zhou et al., 2014). It is therefore possible that *DNMT3A*-mutant CH promotes endothelial dysfunction by epigenetic mechanisms, and might conceivably be amenable to nucleoside analogue treatment.

The hypothesis that CH can contribute to inflammatory conditions is further substantiated by a recent study investigating the impact of donor CH on allogeneic haematopoietic stem cell transplantation (HSCT) outcomes (Frick et al., 2018). Frick et al. found that recipients of CH-positive transplants had a significantly higher rate of chronic graft versus host disease and lower rate of relapse (Frick et al., 2018).

Collectively, these studies suggest a causal link between CH and non-malignant conditions, including leading causes of morbidity and mortality in the general population. It

is therefore possible that CH may prove to be a useful biomarker and/or modifiable risk factor in a range of clinical contexts.

### 3.4 Selection pressures influencing clonal haematopoiesis

Which selective pressures influence somatic evolution in the haematopoietic system? Do certain driver events confer strong enough cell-intrinsic growth advantage that they render clonal expansion inevitable? To what extent do environmental selection pressures determine the fitness advantage conferred by mutations and the pathophysiological outcome of CH? Are any of these selective pressures clinically modifiable? Although these questions remain largely unanswered, it is clear that the incidence and natural history of CH is influenced by clinical context.

### 3.4.1 Ageing

CH prevalence consistently rises with age, which is itself the dominant risk factor for most haematological malignancies (Busque et al., 2018). Haematopoietic ageing is characterised by HSC functional decline and myeloid bias reflected in a tendency towards anaemia and innate and adaptive immune senescence (Pang et al., 2011; Rossi et al., 2007; Rossi et al., 2005). Although HSCs accumulate mutations throughout life, ageing is associated with accelerated accrual of DNA damage (Flach et al., 2014; Osorio et al., 2018; Rossi et al., 2007; Welch et al., 2012). Age-associated genotoxic stress can induce apoptosis or differentiation, thus potentially depleting the functional HSC pool (Adams et al., 2015; Flach et al., 2014; Geiger et al., 2013; Rossi et al., 2007; Yahata et al., 2011). These factors may create an environment where HSCs with greater proliferative capacity or resistance to DNAdamage induced apoptosis and/or terminal differentiation contribute disproportionately to haematopoiesis (Latchney and Calvi, 2017; Pang et al., 2017). Mutations in many recurrent CH drivers, notably DNMT3A, ASXL1 and TET2, may confer a competitive advantage through their ability to increase HSC self-renewal and inhibit differentiation (Abdel-Wahab et al., 2012; Challen et al., 2011; Dominguez et al., 2018; Jeong et al., 2018; Ko et al., 2011; Moran-Crusio, 2011). Similarly, HSC harbouring mutations in TP53 or PPM1D are likely to have a particular competitive advantage in the context of genotoxic stress (Bondar and Medzhitov, 2010; Hsu et al., 2018; Kahn et al., 2018; Wong et al., 2015b).

### 3.4.2 Cytotoxic therapies

Studies of CH in cohorts of cancer patients who have received intensive chemo and/or radiotherapy have demonstrated an elevated prevalence of CH with marked enrichment for *PPM1D* and *TP53* mutated clones (Akbari et al., 2014; Coombs et al., 2017; Gibson et al., 2017; Gillis et al., 2017; Ruark et al., 2013; Takahashi et al., 2017). These findings suggest that exogenous genotoxic stress confers a strong competitive advantage on HSCs harbouring mutations that interfere with the DNA-damage response and apoptosis. In vivo studies of murine HSC competition have demonstrated that cells with *TP53* or *PPM1D* mutations outcompete their wild-type peers in the context of ionising radiation and chemotherapy, respectively (Bondar and Medzhitov, 2010; Hsu et al., 2018; Kahn et al., 2018). CH arising in the context of cancer treatment and its relationship with therapy-related myeloid neoplasms is further discussed in the introduction to chapter 5.

### 3.4.3 Immune-mediated selection

CH is particularly common in the context of bone marrow failure syndromes (Mehta et al., 2010; Reina-Castillon et al., 2017; Stanley et al., 2017; Yoshizato et al., 2015), corroborating the notion that HSC functional decline and depletion promotes cell competition. CH arising in the context of autoimmune-mediated acquired aplastic anaemia (AA) is another example of environmental context influencing HSC somatic evolution (McKerrell and Vassiliou, 2015; Yoshizato et al., 2015). CH is present in the majority of AA patients, and the mutational spectrum reflects the selective pressure exerted by immune attack on HSCs (Stanley et al., 2017; Yoshizato et al., 2015). For example, mutations in PIGA recurrent and result in reduced cell are highly surface expression of glycophosphotidylinositol-anchored autoantigens (McKerrell and Vassiliou, 2015; Yoshizato et al., 2015). Deletion of chromosome 6p, which encompasses human leucocyte antigen alleles, is likely to further aid immune escape (Stanley et al., 2017).

### 4. Sequencing strategies for studying somatic evolution

High resolution insight into somatic evolution in normal ageing tissues requires detection of rare mutations and represents a considerable technical challenge. The Illumina sequencing platform currently has the lowest error rate, though this varies considerably across different genomic regions according to the GC content and other base composition features (Hoang et al., 2016; Ross et al., 2013). With sophisticated post-sequencing analysis techniques, mutations in less error-prone genomic regions can be detected with a sensitivity >0.1%, though this is still inadequate for detecting rare mutations in cells that have not undergone appreciable clonal expansion (Gerstung et al., 2014; Hoang et al., 2016; Martincorena et al., 2015; Ross et al., 2013).

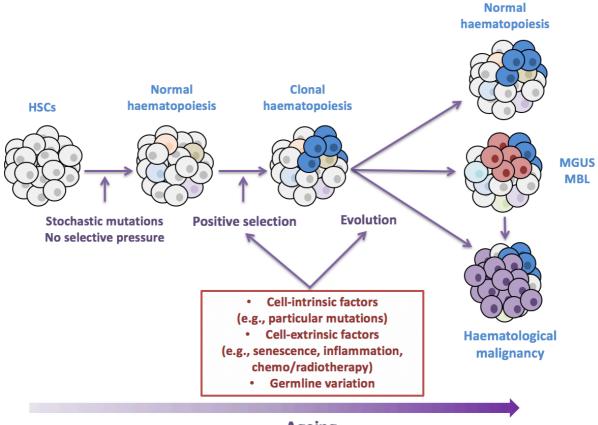

Strategies for overcoming this challenge include growing single-cell derived colonies (Lee-Six et al., 2018) or organoids (Blokzijl et al., 2016; Roerink et al., 2018), laser capture microdissection of clonal units from tissue sections (Moore et al., 2018), single cell sequencing (Navin et al., 2011; Potter et al., 2013; Zong et al., 2012) and error-corrected sequencing using molecular barcodes (Kennedy et al., 2014; Kinde et al., 2011; Mattox et al., 2017). The latter method involves using barcoded adaptors to label both strands from a single DNA molecule. This manoeuvre greatly helps distinguish artefacts (which will almost always be called on one strand only) from real mutations (apparent in both strands from the same DNA molecule)(Kennedy et al., 2014; Schmitt et al., 2012). However, error-corrected sequencing is tractable only for very limited target regions and can be insensitive, in part due to inefficient pull-down of target regions (Kennedy et al., 2014; Schmitt et al., 2012). It is also more labourintensive and expensive due to the need to sequence each individual molecule sufficiently deeply to generate consensus sequences (Kennedy and Ebert, 2017; Kennedy et al., 2014). A main emphasis of the work in this thesis is to better define pathophysiologically significant clonal haematopoiesis, ideally using clinically tractable sampling and sequencing approaches that might eventually be applied in a 'real world' setting. The experiments described here have primarily used bulk peripheral blood and bone marrow samples. For a subset of this work (Chapter 3), we compared the performance of consensus sequencing with molecular barcodes and ultradeep targeted sequencing, which is now routinely available in clinical diagnostic laboratories.

# 5. Thesis Aims

In summary, cancer is a clonal genetic disease adept at evolving resistance to both conventional and targeted therapies (Stratton, 2011; Stratton et al., 2009; Yates and Campbell, 2012). Knowledge of the genetic basis of cancers has galvanised research into early detection using increasingly sensitive sequencing technologies (Cohen et al., 2018; Etzioni et al., 2003; Newman et al., 2016). It is conceivable that earlier detection of asymptomatic, genetically simpler pre-cancerous lesions might enable therapeutic intervention, including targeted therapies for single oncogene addictions, analogous to treatment of chronic phase CML (O'Brien et al., 2003) or therapies to mitigate selection pressures that favour clonal expansion. The success of early cancer detection efforts will hinge upon the ability to distinguish pre-cancer from ubiquitous benign clonal expansions in normal ageing tissues. In the blood system, CH harbouring canonical leukaemia-associated mutations is a risk factor for haematological malignancy (Bowman et al., 2018). However, only a small minority of affected individuals progress, and determinants of evolutionary trajectories remain poorly understood (Figure 1.1). This dissertation investigates the pre-malignant landscape of several common haematological neoplasms and the feasibility of identifying individuals with CH at high risk of developing a blood cancer. The main aims of this project are as follows.

- 1. Describe the premalignant mutational landscape of the commonest haematological neoplasms and compare this with age-related CH in the general population.
- 2. Investigate the extent to which benign clonal haematopoiesis can be distinguished from clones at high risk of malignant transformation.
- 3. Investigate the prevalence of CH in childhood cancer survivors and the natural history of childhood therapy-related myeloid neoplasms.

### Figure 1.1

#### Ageing

#### Figure 1.1 | Initiation and evolution of clonal haematopoiesis

Shown is a model illustrating the process of somatic mutation accumulation in HSCs and different clonal trajectories, with known and hypothetical influences on mutation acquisition and/or positive selection highlighted in red. As yet poorly-defined mutational processes acting on HSCs generate somatic genetic diversity in the HSC pool with time, represented here as a mosaic of distinctly coloured cells. Cells with a relative fitness advantage under the selective pressures prevailing in the haematopoietic microenvironment undergo clonal expansion. Clonal haematopoiesis is a nearly inevitable consequence of ageing, and may play a role in maintaining adequate haematopoiesis in a senescing haemopoietic niche. A minority of individuals may progress to a neoplastic disorder. MGUS, monoclonal gammopathy of unknown significance; MBL, monoclonal B-cell lymphocytosis.

# Chapter 2

# Materials and Methods

# 1. Patient samples

#### 1.1 Pre-AML and control peripheral blood samples (Chapter 3)

For the study of the pre-clinical evolution of AML described in Chapter 3, samples from pre-AML cases and age- and sex-matched controls were collected by collaborators at the European Prospective Investigation into Cancer and nutrition (EPIC) study (Riboli et al., 2002). Samples were divided into discovery and validation cohorts and sequenced at the Wellcome Sanger Institute and the University of Toronto, respectively (see section Methods section 2.1 and 2.2).

Written informed consent was obtained from all participants in accordance with the Declaration of Helsinki and protocols approved by the relevant ethics committees (IARC Ethics Committee approval #14-31, the Weizmann institute of science Ethics board approval #60-1 and East of England - Cambridgeshire and Hertfordshire Research Ethics Committee reference number 98CN01). *De novo* AML patients were identified based on the following ICD9 codes: 9861/3 9860/3 9801/3 9866/3 9891/3 9867/3 9874/3 9840/3 9872/3 9895/3 9873/3. All patients provided peripheral blood samples from which the buffy coat fractions were separated and aliquoted for long-term storage in liquid nitrogen prior to DNA extraction.

#### 1.1.1 Discovery cohort samples

A total of 509 DNA samples were collected from individuals upon enrolment into the EPIC study between 1993 and 1998 across 17 different centres (Riboli et al., 2002). The pre-AML group comprised 95 individuals who developed *de novo* AML an average of 6.37 years (IQR=4.88 years) after the sample was collected. The control group included 414 age and gender matched individuals with no record of haematological disorders (mean follow-up period 11.9 years). The median age at recruitment was 56.75 years (range 36.08 to 74.42). In order to minimize any possible demographic biases, an approximate 1:4.5 pre-AML to control ratio was maintained across the different centres. Discovery cohort (DC) sample metadata is detailed in Appendix 1.

#### 1.1.2 Validation cohort samples

Samples were ascertained from individuals enrolled in the EPIC-Norfolk longitudinal cohort study between 1994 and 2010 (Day et al., 1999). Samples and clinical metadata were available from 37 AML patients (of which 8 were already included in the discovery cohort) and 262 age- and gender-matched controls without a history of cancer or any haematological condition. The median time between the first blood sampling and AML diagnosis was 12.3 years (IQR 8.3 years). The median follow-up period for the control cohort was 17.5 years (IQR 3.8). For 12 individuals in the pre-AML cohort, 2-3 blood specimens were available, taken a median of 3.4 years apart. Of the 262 controls, 141 had multiple blood samples available, spanning a median of 10.5 years. Blood counts and other clinical parameters were available for all study participants (Appendix 2).

#### 1.2 Childhood cancer survivor cohort samples (Chapter 5)

We obtained peripheral blood DNA samples from patients enrolled on long-term follow-up after treatment for a paediatric malignancy and from 3 age-matched controls with no cancer history. Written informed consent was obtained for sample collection and DNA sequencing from all patients or their guardian in accordance with the Declaration of Helsinki and protocols approved by the relevant institutional ethics committees (approval numbers 09REG2015, 1-09/12/2015). The median age at cancer diagnosis was 4.5 years, and the commonest malignancies were acute lymphoblastic leukaemia (n=21), neuroblastoma (n=17) and non-Hodgkin lymphoma (n=10). Nineteen patients had received a hematopoietic stem cell transplant (8 allogeneic and 11 autologous). The median interval between completion of cancer treatment and blood sampling was 6 years (range 2 – 25). Patient characteristics are summarized in Table 4.1 and individual sample details are shown in Appendix 3.

#### 1.3 Paediatric therapy-related myeloid neoplasm samples (Chapter 5)

We obtained bilateral bone marrow biopsies and serial peripheral blood DNA samples from a paediatric neuroblastoma patient who developed a therapy-related myeloid neoplasm. Written informed consent was obtained for sample collection and DNA sequencing from the guardian in accordance with the Declaration of Helsinki and protocols approved by the relevant institutional ethics committees (REC reference 16/EE/0394).

#### 1.4 Pre-lymphoid neoplasm cohort and controls

For the study of the pre-clinical evolution of lymphoid neoplasms (LN) described in Chapter 4, samples from pre-LN cases and age- and sex-matched controls were collected by collaborators at the European Prospective Investigation into Cancer and nutrition (EPIC)-Norfolk study (Day et al., 1999; Riboli et al., 2002).

Written informed consent was obtained from all participants in accordance with the Declaration of Helsinki and protocols approved by the relevant ethics committees (IARC Ethics Committee approval #14-31, East of England - Cambridgeshire and Hertfordshire Research Ethics Committee reference number 98CN01). Pre-LN cases were identified based on the following ICD10 codes: C81\*, C82\*, C83\*, C84\*, C85\*, C86\*, C87\*, C88\*, C89\*, C90\*, C91\*. All patients provided peripheral blood samples from which the buffy coat fractions were separated and aliquoted for long-term storage in liquid nitrogen prior to DNA extraction.

# 2. Library preparation and sequencing

# 2.1 Targeted sequencing of discovery cohort pre-AML and control samples (Chapter 3)

Library preparation and sequencing of discovery cohort samples was performed by Sagi Abelson and colleagues (Princess Margaret Cancer Centre, University Health Network, Toronto). Targeted deep sequencing was performed using error-corrected sequencing (ECS) as detailed below. **Ligation of sequencing adaptors.** Shearing of genomic DNA, preparation of pre-capture sequencing libraries, hybridization-based enrichment, assessment of the libraries quality and enrichment following hybridization were performed as previously described (Newman et al., 2014). Briefly, 100ng of genomic DNA was sheared before library construction (KAPA Hyper Prep Kit #KK8504, Kapa Biosystems) with a Covaris E220 instrument using the recommended settings for 250bp fragments. Following end repair and A-tailing, adapter ligation was performed using 100-fold molar excess of Molecular Index Adapter. Library clean-up was performed with Agencourt AMPure XP beads (Beckman-Coulter) and the ligated fragments were then amplified for 8 cycles using 0.5µM Illumina universal and indexing primers.

**Target capture.** Targeted capture was carried out on pools containing 3 indexed libraries. Each pool of adaptor-ligated DNA was combined with 5µl of 1mg/ml Cot-I DNA (Invitrogen), and 1 nmol each of xGEN Universal Blocking Oligo – TS-p5, and xGen Universal Blocking Oligo – TS-p7 (8nt). The mixture was dried using a SpeedVac and then re-suspended in 1.1µl water, 8.5µl NimbleGen 2× hybridization buffer and 3.4µl NimbleGen hybridization component A. The mixture was heat denatured at 95°C for 10 minutes before addition of 4µL of xGen Lockdown Probes (xGen<sup>®</sup> AML Cancer Panel v1.0, 3pmol). The panel was designed to include all genes recurrently mutated in the 2013 TCGA study of AML (TCGA et al., 2013). Each pool was then hybridized at 47°C for 72 hr. Washing and recovery of the captured DNA was performed according to the manufacturer's specifications. Briefly, 100µl of clean streptavidin beads was added to each capture. Following separation and removal of supernatant on a magnet, 200µL 1X Stringent Wash Buffer was added and the reaction was incubated at 65°C for 5 min. Supernatant containing unbound DNA was removed before repeating the high stringency wash one additional time. Next, the bound DNA was washed as follows: 1) 200µl 1X Wash Buffer I and separation of the supernatants by magnetic separation, 2) 200µl 1X Wash Buffer II following magnetic separation, 3) 200µl 1X Wash Buffer III and removal of the supernatants using magnetic separation. The captured DNA on beads was resuspended in 40µl of Nuclease-Free water before dividing the total volume into 2 PCR tubes and subjecting the libraries to 10 cycles of post-capture amplification (manufacturer recommended conditions; Kapa Biosystems). Prior to sequencing, libraries were spiked in with 2% PhiX.

# 2.2 Targeted sequencing of validation cohort pre-AML and control samples and AML diagnostic specimens (Chapter 3)

This section describes the sequencing methods for the validation cohort (VC) pre-AML and control samples discussed in Chapter 3.

Targeted sequencing was performed using a custom cRNA bait set (SureSelect, Agilent, UK, ELID #0537771, contributed by Dr Elli Papaemmanuil and Dr Peter Campbell) designed complementary to all coding exons of 111 genes implicated in myeloid leukaemogenesis (Appendix 4). Genomic DNA was sheared using the Covaris M220. Equimolar pools of 10 libraries were prepared and sequenced on the Illumina HiSeq 2000 using 75 base paired-end sequencing as per Illumina and Agilent SureSelect protocols.

#### 2.3 Multiplex PCR design and sequencing (Chapter 5)

This section describes the sequencing strategy used to screen peripheral blood samples from childhood cancer survivors for clonal haematopoiesis (Chapter 5). The multiplex PCR panel was designed by Dr Naomi Park and Dr George Vassiliou as detailed in a published protocol (Park and Vassiliou, 2017) and I performed PCR experiments with supervision from Dr Park. Primers were designed using mprimer software (Shen et al., 2010) and checked for specificity using MFEprimer (Qu and Zhang, 2015). In order to minimise primer dimer formation, primers were synthesised to include a single 2'-O-Methyl base substitution, one base from the 3'-end. The multiplex PCR amplifies 32 regions of 14 genes frequently mutated in CH or t-MN (Table 4.2) (Bowman et al., 2018; McNerney et al., 2017). This is an extension of a previously validated assay (McKerrell et al., 2015) to include all coding exons of *TP53* and *PPM1D*, genes implicated in t-MN pathogenesis (Gibson et al., 2017; Hsu et al., 2018; McNerney et al., 2017). Primer sequences are detailed in Appendix 5. Amplicon libraries were sequenced on the Illumina MiSeq platform as detailed in Park et al. (Park and Vassiliou, 2017).

#### 2.4 Targeted sequencing using a custom pan-haematological cancer panel

This section describes the sequencing methods for the diagnostic AML bone marrow samples discussed in Chapter 3, the pre-lymphoid cancer specimens and controls discussed in Chapter 4 and the paediatric therapy-related myeloid neoplasm described in Chapter 5. Targeted sequencing was performed using a custom cRNA bait set (SureSelect, Agilent, UK, ELID ID: 3129591) designed complementary to all coding exons of 95 genes recurrently mutated in myeloid and lymphoid haematological cancers, including the genes most frequently implicated in paediatric MPN/MDS (Appendix 6). Genes implicated in lymphoid neoplasms were selected with input from Dr Philip Beer. Genomic DNA was sheared using the Covaris M220. Equimolar pools of 10 libraries were prepared and sequenced on the Illumina HiSeq 2000 using 75 base paired-end sequencing as per Illumina and Agilent SureSelect protocols.

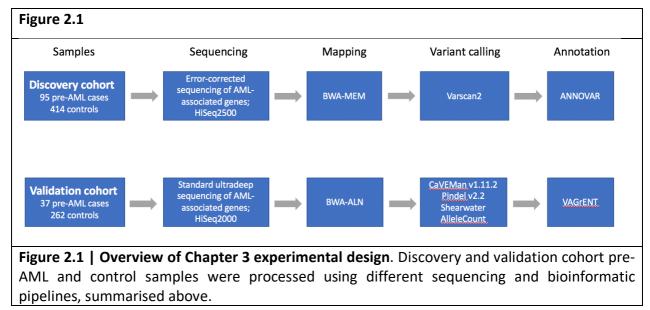

#### 2.5 Whole genome sequencing

Whole genome sequencing of peripheral blood DNA (Chapter 5) was performed by 150bp- paired-end sequencing on the Illumina Hiseq X10 platform. The Illumina no-PCR protocol was followed to construct short insert libraries, prepare flow cells and generate clusters (Kozarewa et al., 2009).

# 3. Variant calling

#### 3.1 Variant calling in pre-AML and control samples

Variant filtering and annotation for the discovery cohort (section 3.1.1) and validation cohort (section 3.1.2) was performed by Dr Sagi Abelson and myself, respectively. After filtering and annotation, both datasets were combined and driver mutation calling and additional artefact filtering was performed by me as detailed in sections 3.1.3 and 3.1.4.

#### 3.1.1 Discover cohort variant calling and error correction

126bp paired-end read sequencing data from the Illumina HiSeq2500 platform was converted to fastq format. The 2bp molecular barcode information of each read was trimmed and incorporated into the read name. The thymine nucleotide required for ligation was removed from the sequences. The processed FASTQ files were then aligned to the hg19 reference genome using the Burroughs-Wheeler Aligner (BWA-MEM) (Li and Durbin, 2010). Indel-re-alignment was performed using GATK (McKenna et al., 2010). An in-house algorithm was written to collapse read families that share the same molecular barcode sequence, the left most genomic position of where each read of the pair maps to the reference and the CIGAR string. Families comprised of at least 2 reads were used to generate consensus reads (CR) and a consensus base was called when there was at least 70% agreement. When a consensus base was called, it was assigned with the maximum base quality score observed in its corresponding pre-collapsed reads. Furthermore, when possible, duplex reads (DR) were generated from two CR, from a singleton read (SR) and a CR, or from two SR (Kennedy et al., 2014). For each sequenced sample, we generated two BAM files, called bam1 and bam2. Bam1 consists of DR, CR and singleton reads, thereby including some error corrected and nonerror corrected reads. Bam2 consists of DR and CR but not singleton reads. Both files were then analysed to detect single nucleotide variants (SNVs) and small insertions and deletions (indels) using Varscan2 (Koboldt et al., 2012). In order to further remove sequencing artefacts and improve sensitivity, we applied a two-step statistical polishing approach that models the error rate at each sequenced genomic position. For both steps, bam1 was used and all the samples except the sample being investigated were included for error rate modelling. At step one, as previously described (Newman et al., 2014), the error rates were modelled by fitting weibull distribution curves to the non-reference allele fractions. SNVs with allele fractions that were statistically distinguishable from the background error rates were further analysed. At Step 2, the coverage of the non-reference allele fractions was considered by using linear line fitting that describes the negative correlation that exist between the log (non-reference allele fraction) and the corresponding log(coverage) values. This allowed us to estimate different error rates at different coverage depths. Indel errors were filtered using barcode mediated error correction alone. At least 10 CR, 5 supporting reads on the forward strand, 5 supporting reads on the reverse strand, and 2 DR were required to call an indel. Variants were

annotated using Annovar (Yang and Wang, 2015). Additional post-processing steps applied to data from both the discovery and validation cohorts are detailed in section 3.1.3.

#### 3.1.2 Validation cohort variant calling

Sequencing reads were aligned to the reference genome (GRCh37d5) using the Burrows-Wheeler aligner (BWA-ALN)(Li and Durbin, 2009). Unmapped reads, PCR duplicates and reads mapping to regions outside the target regions (merged exonic regions + 10bp either side of each exon) were excluded from analysis. Sequencing depth at each base was assessed using Bedtools coverage v2.24.0 (Quinlan and Hall, 2010).

#### Substitutions

Somatic single nucleotide variants (SNVs) were called using Shearwater, an algorithm developed for detecting subclonal mutations in deep sequencing experiments (https://github.com/gerstung-lab/deepSNV v1.21.5) (Gerstung et al., 2012; Gerstung et al., 2014; Martincorena et al., 2015) considering only reads with minimum nucleotide and mapping quality of 25 and 40, respectively. This algorithm models the error rate at individual loci using information from multiple unrelated samples. Additionally, allele counts at the recurrent AML mutation hotspots listed in section 3.1.4 were generated using an in-house script (https://github.com/cancerit/alleleCount) and manually inspected in the Jbrowse genome browser (Buels et al., 2016). To further complement our SNV calling approach, we applied an extensively validated in-house version of CaVEMan v1.11.2 (Cancer Variants through Expectation Maximization)(Stephens et al., 2012). CaVEMan compares sequencing reads between study and nominated normal samples and uses a naïve Bayesian model and expectation-maximization approach to calculate the probability of a somatic variant at each base (https://github.com/cancerit/CaVEMan). Post-processing filters required that the following criteria were met for CaVEMan to call a somatic substitution:

- If coverage of the mutant allele was less than 8, at least one mutant allele was detected in the first 2/3 of the read.
- Less than 3% of the mutant alleles with base quality ≥ 15 were found in the nominated normal sample.
- 3) Mean mapping quality of the mutant allele reads was  $\geq$  21.

46

- 4) Mutation does not fall in a simple repeat or centromeric region.
- 5) Fewer than 10% of the reads covering the position contained an indel according to mapping.
- 6) Less than 80% of the reads report the mutant allele at the same read position.
- At least a third of the reads calling the variant had a base quality of 25 or higher.
- 8) Not all mutant alleles reported in the second half of the read.
- 9) Position does not fall within a germline insertion or deletion.

The following additional post-processing criteria were applied to all SNV calls:

- 1) Minimum VAF 0.5% with a minimum of 5 bidirectional reads reporting the mutant allele (with at least 2 reads in forward and reverse directions).
- 2) No indel called within a read length (75bp) of the putative substitution.

#### Small insertions and deletions

Small insertions and deletions were sought using two complementary approaches. Firstly, an in-house version of Pindel v2.2 (Raine et al., 2015) (https://github.com/cancerit/cgpPindel) was applied. We additionally used the aforementioned Shearwater algorithm (Gerstung et al., 2012; Gerstung et al., 2014; Martincorena et al., 2015) in order to increase sensitivity for indels present at low VAF. VAF correction was performed using an in-house script (https://github.com/cancerit/vafCorrect). Post-processing filters required that the following criteria were met for a variant to be called:

- Minimum of 5 reads supporting the variant with minimum of 2 reads in each direction. For Pindel, the total read count was based on the union of BWA and Pindel reads reporting the mutant allele.
- 2) Minimum VAF 0.5%
- Variant not present within an unmatched normal panel of approximately 400 samples.
- 4) No reads supporting the variant identified in the nominated normal sample.

Mutations were annotated according to ENSEMBL version 58 using VAGrENT (Menzies et al., 2002) for transcript and protein effects (https://github.com/cancerit/VAGrENT) and Annovar (Yang and Wang, 2015) for additional functional annotation.

#### 3.1.3 Additional post-processing filters applied to all data

The following variants were flagged for additional inspection for potential artefacts, germline contamination or index-jumping event:

- 1) Any mutant allele reported within 75bp of another variant.
- Any mutant allele with a population allele frequency > 1 in 1000 according to any of five large polymorphism databases: ExAC, 1000 Genomes Project, ESP6500, CG46, Kaviar that is not a canonical hotspot driver mutation with COSMIC recurrence > 100.
- Mutations that were present in > 10% of the control cohort but not recurrent in COSMIC were flagged as potential germline variants or sequencing artefact.
- As artefactual indels tend to be recurrent, any indels occurring in >2 samples were flagged for additional inspection.

#### 3.1.4 Curation of oncogenic variants

Putative oncogenic variants were identified according to evidence for functional relevance in AML as previously described and used to define CH-PD (Gerstung et al., 2017; Papaemmanuil et al., 2016).

Variants were annotated as likely driver events if they fulfilled any of the following criteria:

- 1) Truncating mutations (nonsense, essential splice site or frameshift indel) in the following genes implicated in AML pathogenesis by loss-of-function: *NF1, DNMT3A, TET2, IKZF1, RAD21, WT1, KMT2D, SH2B3, TP53, CEBPA, ASXL1, RUNX1, BCOR, KDM6A, STAG2, PHF6, KMT2C*.
- 2) Truncating variants in CALR exon 9.
- 3) JAK2 V617F
- 4) FLT3 ITD

- 5) Non-synonymous variants at the following hotspot residues:
  - a. CBL E366, L380, C384, C404, R420, C396
  - b. DNMT3A R882
  - c. FLT3 D835
  - d. IDH1 R132
  - e. IDH2 R172, R140
  - f. *KIT* W557, V559, D816
  - g. KRAS A146, Q61, G13, G12
  - h. MPL W515
  - i. NRAS Q61, G12, G13
  - j. SF3B1 K700, K666
  - k. SRSF2 P95
  - l. U2AF1 Q157, R156, S34
- Non-synonymous variants reported at least 10 times in COSMIC with VAF < 42% and population allele frequency < 0.003.</li>
- 7) Non-synonymous variants clustering within a functionally validated domain or within 4 amino acids of a hotspot variant with population allele frequency < 0.003 and VAF < 42%.</p>
- Non-synonymous variants reported in COSMIC > 100 times with population allele frequency < 0.003 regardless of VAF.</li>

This driver curation strategy inevitably runs a small risk of including germline variants in familial AML genes, e.g., *RUNX1*. However, in most settings, where a matched constitutional DNA sample is likely to be unavailable, this seems the best approach.

Of note, the entire validation cohort included 37 pre-AMLs, 8 of these were also included in the original discovery cohort and therefore were excluded from the validation cohort for downstream analysis. Both the discovery and the validation cohorts sourced samples from different centres participating in the EPIC study, hence the overlap. However, discovery and validation cohorts were sequenced by two independent research groups using different methods, as described above. Putative driver mutations detected for the duplicated samples by the two different methods were highly similar. All 9 driver mutations detected in the discovery cohort with VAF>0.015 were detected in the validation cohort samples, while 8 other mutations (7 in TET2 or DNMT3A) with lower VAFs escaped validation. The latter is probably due to the higher VAF cut-off applied to the validation cohort sequencing method and the stochastic failure to sample a small clone in two independent experiments.

#### 3.2 Variant calling from multiplex PCR sequencing

Reads were aligned to human genome build GRCh37d5 using the Burrows-Wheeler Aligner (Li and Durbin, 2010) and analysed for somatic single nucleotide variants and indels. Allele counts across target hotspots were generated using an in-house script (https://github.com/cancerit/alleleCount), considering only loci with  $\geq$ 1000 reads and minimum base and mapping quality of 25 and 35, respectively. In order to identify SNV and indels in *TP53* and *PPM1D*, 3 variant callers were applied: Shearwater (https://github.com/gerstung-lab/deepSNV v1.21.5)(Gerstung et al., 2012; Gerstung et al., 2014; Martincorena et al., 2015), cgpPindel v2.2 (Raine et al., 2015) and CaVEMan v1.11.2 (Cancer Variants through Expectation Maximization, https://github.com/cancerit/CaVEMan)(Stephens et al., 2012) as describe in section 3.1.2 above.

#### 3.3 Variant calling for non-AML pre-malignant samples and controls

SNV and indel calling was performed as described in 3.1.2 and 3.1.3. The strategy for curating putative driver variants was adjusted to account for the greater number of genes included in the larger bait panel (Appendix 6). Specifically, variants were flagged as candidate driver events if they fulfilled any of the following criteria:

- 1) Nonsense or frameshift mutations in the following genes: *ARID1A, ASXL1, ATM, B2M, BCOR, BCORL1, CALR, CDKN2A, CEBPA, CREBBP, CSF1R, CSF3R, CUX1, DNMT3A, EP300, FBXW7, KDM6A, KMT2C, KMT2D, NF1, NOTCH2, NPM1, PAX5, PHF6, POT1, PPM1D, PRDM1, PTEN, RAD21, SETD2, SOCS1, STAG2, TET2, TNFAIP3, TNFRSF14, TP53, WT1, ZRSR2*
- 2) Splice site mutations in the following genes: ARID1A, ATM, BCOR, CBL, CD79B, CDKN2A, CUX1, DNMT3A, KDM6A, NF1, PAX5, PHF6, PRDM1, PTEN, SETD2, STAG2, WT1, ZRSR2

50

- 3) Missense mutations in the following genes were considered if they passed SNP and artefact filters and had support as candidate drivers based on relevant literature (Tate et al., 2019): *ARID1A, ASXL1, ATM, B2M, BCL6, BCORL1, BRAF, CALR, CARD11, CBL, CD79B, CDKN2A, CEBPA, CREBBP, CSF1R, CSF3R, CUX1, DNMT3A, EP300, ETNK1, EZH2, FBXW7, FLT3, GATA2, GNAS, H3F3A, IDH1, IDH2, IL7R, JAK2, KIT, KMT2D, KRAS, MPL, MYD88, NF1, NOTCH1, NOTCH2, NRAS, PAX5, PDGFRA, PHF6, PIM1, POT1, PPM1D* (exon 6), *PRDM1, PTEN, PTPN11, RAD21, SETBP1, SETD2, SF3B1, SRSF2, STAG2, STAT3, TET2, TNFRSF14, TP53, U2AF1, WT1, XPO1, ZEB1, ZRSR2*
- Non-synonymous variants reported at least 10 times in COSMIC with VAF < 35% and population allele frequency < 0.003.</li>
- Non-synonymous variants clustering within a functionally domain or within 4 amino acids of a hotspot variant with population allele frequency < 0.003 and VAF < 35%.</li>
- Non-synonymous variants reported in COSMIC > 150 times with population allele frequency < 0.003 regardless of VAF.</li>

#### 3.4 Screening for pathogenic germline variants

All mutations flagged by SNP filters (VAF > 0.42 and present in ExAC, 1000 Genomes Project, ESP6500, CG46 or Kaviar databases) were screened against the ClinVar database (Landrum et al., 2016) and Human Gene Mutation Database (HGMD) (Stenson et al., 2003) to identify potential cancer predisposition germline variants.

#### 3.5 Variant calling from whole genome sequences (Chapter 5)

Whole genome sequences were mapped to the GRCh37d5 reference genome using the Burroughs-Wheeler Aligner (BWA-mem) (Li and Durbin, 2010). The Cancer Genome Project (Wellcome Trust Sanger Institute) variant calling pipeline was used to call somatic mutations which includes the following algorithms: CaVEMan (1.11.0)(Jones et al., 2016) for substitutions; an in-house version of Pindel (2.2.2; github.com/cancerit/cgpPindel)(Raine et al., 2015) for indels; BRASS (5.3.3; github.com/cancerit/BRASS) for rearrangements (Li et al., 2017), and ASCAT NGS (4.0.0) for copy number aberrations (Van Loo et al., 2010). In addition to filters inherent to the CaVEMan algorithm, the following post-processing filtering criteria were applied for substitutions: a minimum two reads in each direction reporting the mutant allele; at least ten fold coverage at the mutant allele locus; minimum variant allele fraction 5%; no insertion or deletion called within a read length (150bp) of the putative substitution; no soft-clipped reads reporting the mutant allele; median BWA alignment score of the reads reporting the mutant allele  $\geq$  140. The following variants were flagged for additional inspection for potential artefacts, germline contamination or index-jumping event: any mutant allele reported within 150bp of another variant; any mutant allele with a population allele frequency > 1 in 1000 according to any of five large polymorphism databases: ExAC, 1000 Genomes Project, ESP6500, CG46, Kaviar.

To identify potential driver events in whole genome data, I considered variants presenting in established cancer genes (Tate et al., 2019). Tumour suppressor coding variants were considered if they were annotated as functionally deleterious by an in-house version of VAGrENT (http://cancerit.github.io/VAGrENT/) (Menzies et al., 2002), or alternatively if they were disruptive rearrangement breakpoints or homozygous deletions. Additionally, homozygous deletions were required to be focal (<1 Mb in size) or constitute a known contiguous gene syndrome implicated in t-MN (McNerney et al., 2017). Mutations in oncogenes were considered driver events if they were located at previously reported canonical hot spots (point mutations) or amplified the intact gene. Amplifications also had to be focal (<1 Mb) and increase the copy number of oncogenes to a minimum of 5 copies.

#### 3.6 Copy number variation in targeted sequencing data

To detect copy number aberrations in the paediatric t-MN case discussed in Chapter 5, I applied FACETS (Fraction and Allele-Specific Copy Number Estimates from Tumor Sequencing), an allele-specific copy number analysis (ASCN) method (Shen and Seshan, 2016).

## 4. Predictive modelling

Regularised logistic and Cox proportional hazards regression approaches were tested in generating the predictive models described in Chapters 3 and 4.

Dr Moritz Gerstung wrote the initial version of the code for Chapter 3 and closely supervised all further iterations of the models described in Chapter 3. The code for the models described in Chapter 4 was written by me using a very similar analysis framework and methods as in Chapter 3.

#### 4.1 Cox proportional hazards model with random effects

We used a Cox proportional hazards regression to model haematological malignancyfree survival as previously described (Gerstung et al., 2017). We used random effects for the Cox proportional hazards model in the CoxHD R package developed by Dr Gerstung (http://github.com/gerstung-lab/CoxHD). A key strength of this approach is the ability to include many variables in one model while shrinking estimated effects for parameters with weak support in the data, thus controlling for overfitting. We used weighting to minimise the biases introduced by the artificial case-control ratio (Antoniou et al., 2005) and calculated hazard ratios relative to the (approximate) true cumulative incidence of either AML (Chapter 3) or all lymphoid malignancies (Chapter 4) in the given age range over a follow up of 10-20 years. Full details of model derivation and comparisons with alternative methods are included in the accompanying code (Appendix 7). In brief, variables comprised age, gender, the variant allele fraction of putative driver mutations and selected clinical variables when available. We performed agnostic imputation of missing variables by mean and linear rescaling of gene variables by a power of 10 to a magnitude of 1.

All blood samples taken within 6 months of cancer diagnosis were excluded from model training. Among the pre-AML samples (Chapter 3), 4 individuals were thus removed from the discovery cohort. For one individual in the validation cohort who provided 3 prediagnostic samples, the 3rd sample was taken within this time frame and was also excluded (though their older samples allowed this individual to remain in the modelling analysis).

For each model, the following measures of predictive accuracy were evaluated before and after leave-one-out cross-validation (LOOCV): (i) concordance (C)(Harrell et al., 1996), (ii) time-dependent area under the receiver-operating characteristic curve (AUC)(O'Quigley et al., 2005) and (iii) Uno's estimator of cumulative/dynamic AUC (Uno et al., 2007). Coefficient confidence intervals were calculated using 100 bootstrap samples.

Concordance measures were obtained using the survConcordance() function implemented in the survival R package (Therneau and Grambsch, 2000). Dynamic AUC was calculated with AUC.uno() implemented in the survAUC package (Heagerty et al., 2000). Timeindependent AUC was calculated by the performance function implemented in the ROCR package (Sing et al., 2005). The expected incidence of each haematological malignancy was calculated from the UK office of national statistics, available at http://www.cancerresearchuk.org/health-professional/cancer-statistics/statistics-bycancer-type/. All-cause mortality data was obtained from the office of national statistics (https://www.ons.gov.uk/).

#### 4.2 Ridge regularised logistic regression

Using the same covariates as in the Cox proportional hazard models, we fitted a ridge regularised logistic regression model to dichotomised outcome data. While logistic regression is a common choice for case-control analyses, a downside of this approach is the inability to explicitly use time-dependent covariates. The penalty parameter was chosen using LOOCV on the full cohort; this value was then used on the discovery and validation cohorts to yield the same scaling of coefficients. Confidence intervals were calculated using 100 bootstrap samples. Fitting was performed using the glmnet R package (Simon et al., 2011). AUC as the primary performance metric was calculated using the ROCR R package (Sing et al., 2005).

# Chapter 3

# Predicting acute myeloid leukaemia risk in the general population

# 1. Introduction

As discussed in Chapter 1, CH harbouring canonical leukaemia-associated mutations is a risk factor for haematological malignancy, though only a small minority of affected individuals progress (Bowman et al., 2018). Acute myeloid leukaemia (AML) is the commonest acute leukaemia in adults and typically presents suddenly as a fulminant disease with a poor prognosis (Döhner et al., 2015). This chapter describes an experiment to distinguish individuals at high risk of developing *de novo* acute myeloid leukaemia (AML) from those with indolent CH at low risk of malignant transformation. The introduction provides background on AML and reviews existing literature on its pre-clinical evolution and relationship to clonal haematopoiesis.

#### 1.1 Acute myeloid leukaemia

#### 1.1.1 Definition and epidemiology

AML is an aggressive haematopoietic stem cell disorder characterized by clonal proliferation of poorly differentiated myeloid cells (Döhner et al., 2015). It is the commonest acute leukaemia among adults, and comprises around 20% of all paediatric leukaemia (Döhner et al., 2015). The incidence of AML increases dramatically with age, and exceeds 100 cases per 100,000 in those over the age of 60, with a higher risk among men (CRUK, 2018;

SEER, 2018). There are around 3,100 new AML cases and 2,500 AML-related deaths each year in the UK (CRUK, 2018).

#### 1.1.2 Aetiology and risk factors

The dominant AML risk factor is age, though the role ageing plays in the aetiology of AML is incompletely understood (Döhner et al., 2015). The somatic mutation burden seen in AML correlates with age at diagnosis and is similar to that observed in normal HSCs from agematched individuals without a haematological disorder (Welch et al., 2012). Unlike many common adult epithelial cancers, the role of extrinsic mutational processes appears to be minor, with the age-related mutational SBS11 and SBS5 accounting for the vast majority of AML mutations (Alexandrov et al., 2018; Alexandrov et al., 2013).

Environmental or occupational chemical exposures, notably to benzene and other industrial solvents, may play a role in a minority of AML cases, though evidence for a causal link is weak (Austin et al., 1988).

Germline variants in a growing number of genes have been implicated in myeloid malignancies, including *RUNX1, GATA2, TERT, ATG2B, TP53* and *CEBPA* (Hinds et al., 2016; Saliba et al., 2015; Smith et al., 2004; Zhang et al., 2015). As discussed in the general introduction, germline and somatic mutations in the same cancer gene generally carry different biological and clinical significance and merit distinction (Arber et al., 2016; Döhner et al., 2015). Furthermore, recent evidence has suggested that the distinction between germline and somatic mutation is less clear than previously thought, with a growing catalogue of highly penetrant germline variants strongly predisposing to acquisition or clonal selection of particular somatic mutations (Hinds et al., 2016; Loh et al., 2018).

Other myeloid neoplasms, most commonly myeloproliferative neoplasms and myelodysplastic syndromes, may transform into AML, termed secondary AML (sAML) (Deininger et al., 2017; Sperling et al., 2017).

The most prevalent extrinsic risk factor for AML is previous exposure to chemotherapy or radiotherapy, in particular alkylating agents and topoisomerase II inhibitors (McNerney et al., 2017). Any AML that arises after cytotoxic treatment is termed therapy-related AML (t-AML) and is discussed further in the introduction to Chapter 5.

56

AML that presents suddenly with manifestations of bone marrow failure is termed *de novo* AML to distinguish it from sAML and t-AML, although, as discussed later on, these distinctions are not always straight-forward or biologically meaningful.

#### 1.1.3 AML genetics

The genetic diversity of AML was first revealed by cytogenetic analyses in the 1970s (Rowley, 2008), and has since been well characterised by several large genomic studies (Arber et al., 2016; Gerstung et al., 2017; Papaemmanuil et al., 2016; TCGA et al., 2013). According to the classic "two-hit" model of AML leukaemogenesis proposed by Gilliland and Griffin, two types of mutations are required to produce AML: type II mutations that impair differentiation and subsequent apoptosis and are typically initiating events, and type I mutations that endow pre-leukaemic clones with a proliferative advantage (Gilliland and Griffin, 2002). Genomic studies have corroborated the main concepts of this model, providing further evidence that the block in differentiation is the initiating event for *de novo* AML. Many of the commonest mutations in AML founding clones target epigenetic regulators (Kronke et al., 2013; Shlush et al., 2014; Welch, 2014), which play central roles in haematopoietic stem cell differentiation (Abdel-Wahab et al., 2012; Challen et al., 2011; Figueroa et al., 2010a; Figueroa et al., 2010b). Furthermore, leukaemia-associated mutations in epigenetic regulators are common drivers of CH, whereas 'type I' mutations are very rarely observed in association with CH, consistent with this class of genetic events occurring later in leukaemogenesis after differentiation arrest has been established (Genovese et al., 2014; McKerrell et al., 2015; Xie et al., 2014).

Although this model remains conceptually useful, sequencing studies have revealed diverse genetic routes to AML, with recurrent mutations identified in over 70 genes (Papaemmanuil et al., 2016; TCGA et al., 2013). The majority of patients harbour multiple driver events, and both individual mutations and co-occurrence patterns are powerful determinants of clinical outcome (Gerstung et al., 2017; Huet et al., 2018; Papaemmanuil et al., 2016). The most recurrent structural and numerical chromosomal abnormalities include t(8;21), inv(16), t(15;17), 11q (MLL) fusions, inv(3), t(6;9), -7/7q, +8/8q, -5/5q and -17/17p (Papaemmanuil et al., 2016; TCGA et al., 2013). The majority of driver events in adult AML, however, are point mutations (single nucleotide variants and indels)(Papaemmanuil et al., 2016; TCGA et al., 2013). Frequently mutated genes include epigenetic regulators (*DNMT3A*,

*TET2, IDH1, IDH2*), genes involved in the RNA splicing machinery (*SF3B1, SRSF2, U2AF1, ZRSR2*), chromatin regulators (*ASXL1, BCOR, STAG2, MLL-PTD, EZH2, PHF6*), transcription factors (*RUNX1, GAT2, CEBPA*), *NPM1*, and genes involved in RAS and/or STAT signalling (*NRAS, KRAS, PTPN11, NF1, FLT3, CBL, KIT*)(Papaemmanuil et al., 2016; TCGA et al., 2013).

#### 1.1.4 AML classification schemes

The World Health Organisation (WHO) Classification of Haematopoietic and Lymphoid Tissues subdivides AML into four categories: AML with recurrent genetic abnormalities, AML with myelodysplasia-related changes, therapy-related AML and AML not otherwise specified (NOS)(Arber et al., 2016). The latter group is further subdivided by morphological features. The WHO classification scheme was updated in 2016 to include several new disease categories within the section of AML with recurrent genetic abnormalities (Arber et al., 2016). However, several studies suggest that WHO subgroups still do not adequately capture the molecular heterogeneity of AML, which underpins its biological and prognostic features (Gerstung et al., 2017; Metzeler et al., 2016; Papaemmanuil et al., 2016). The largest genomic study of AML to date included 1540 patients enrolled in three prospective clinical trials and identified eleven prognostically relevant molecular-genetic subgroups (Gerstung et al., 2017; Papaemmanuil et al., 2016). This study added considerable nuance to our understanding of AML biological mechanisms and genetic classification. For example, mutations affecting different loci in the same gene, e.g., *IDH2* p.R140 and *IDH2* p.R172, had divergent cooccurrence patterns and impacts on clinical outcome.

#### 1.1.5 Treatment challenges

Despite much progress in understanding AML genetics and pathogenesis, standard AML therapy has changed very little over the past three decades (Döhner et al., 2015; Yates et al., 1973). The backbone of therapy remains the combination of two drugs developed in the 1950s, namely daunorubicin and cytarabine, compounds serendipitously derived from soil microbes and marine sponges, respectively (Schwartsmann et al., 2001; Stutzman-Engwall and Hutchinson, 1989). Improvements in patient outcomes are primarily attributable to better supportive care during periods of myelosuppression (Döhner et al., 2015). Although most patients capable of tolerating intensive chemotherapy achieve remission, the majority

succumb to relapse (Döhner et al., 2015; Rubnitz et al., 2014). Overall survival rates are 35% to 40% for younger patients and 5% to 15% for patients over the age of 60 (Dohner et al., 2010; Rubnitz et al., 2014). Efforts to target recurrently mutated oncogenes, notably the tyrosine kinases FLT3 and KIT, have been met with rapid emergence of disease resistance and little improvement in overall survival (Döhner et al., 2015; Stein, 2015; Wander et al., 2014).

#### 1.2 The relationship between CH and AML

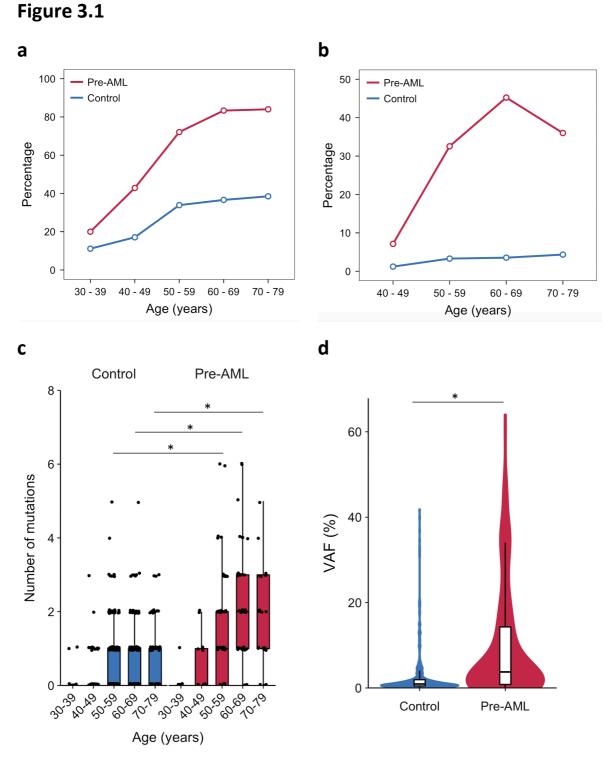

As discussed in Chapter 1, the two largest studies of clonal haematopoiesis in the general population demonstrated an increased risk of haematological cancers in general (not specifically AML) in those with CH, which was higher in those with mutations at high VAFs (Genovese et al., 2014; Jaiswal et al., 2014). Genovese et al. identified thirty-one participants diagnosed with a hematologic cancer more than 6 months after DNA sampling, of whom thirteen (42%) had antecedent CH (Genovese et al., 2014). Of these, two developed AML and one developed "acute leukemia of unspecified origin". Of the remaining ten, three developed CLL, two MPN (both JAK2 V617F mutated), one B-cell lymphoma, one multiple myeloma, one monoclonal gammopathy of unknown significance, one CMML and one MDS (Genovese et al., 2014). Two of the three MDS/AMLs in this paper were diagnosed within two months after DNA sampling (Genovese et al., 2014). Furthermore, Genovese et al. found that CH with putative drivers (CH-PD) afforded the same risk of haematological cancers as CH without known drivers, potentially alluding to indirect risks associated with CH (Jaiswal et al., 2014). Similarly, Jaiswal et al. reported sixteen haematological cancers during a median 95-month follow-up period, of which only five (31%) had CH detected in their pre-diagnosis sample (Jaiswal et al., 2014). Of these, two developed lymphoma, one "cancer of the spleen" (JAK2 V617F mutated), one "myeloid leukaemia" and one "leukaemia" not otherwise specified (Jaiswal et al., 2014). Together, these two studies captured up to five possible AMLs amongst 29,652 study participants (Genovese et al., 2014; Jaiswal et al., 2014). Collectively, only a minority of blood cancers arising during follow-up were diagnosed in individuals with antecedent CH, and several of these were indolent myeloproliferative or chronic lymphoid conditions. It therefore remained unclear whether or not CH could be used to predict the subsequent development of blood cancers, let alone of *de novo* AML, with any degree of sensitivity or specificity.

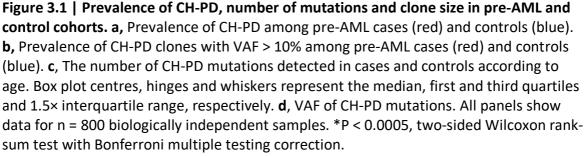

## 2. Results

To investigate whether individuals at high risk of developing *de novo* AML can be distinguished from those with benign CH, genes recurrently mutated in AML or CH were deep-sequenced in peripheral blood cell DNA from a total of 125 individuals sampled before AML diagnosis (pre-AML group), together with 676 unselected age- and gender-matched individuals (control group). To detect somatic mutations with maximum sensitivity, deep error-corrected targeted sequencing was first applied to a discovery cohort of 95 pre-AML cases sampled on average 6.3 years before AML diagnosis and 414 age- and gender-matched controls (Appendix 1). Error-corrected sequencing was performed by Dr Sagi Abelson as detailed in Methods section 2.1. A validation cohort comprising 29 pre-AML cases and 262 controls (Appendix 2) was analysed using conventional deep sequencing with an overlapping gene panel (Methods section 2.2).

#### 2.1 Prevalence of CH-PD in pre-AML versus controls

Taking both cohorts together, CH, defined by the presence of mutations in putative driver genes (CH-PD), was found in 73.4% of the pre-AML cases at a median of 7.6 years before diagnosis (Appendices 8 and 9). By contrast, CH-PD was observed in 36.7% of controls ( $P < 2.2 \times 10^{-16}$ , two-sided Fisher's exact test; Figure 3.1a). This CH-PD prevalence in the controls is consistent with data from a study of more than 2,000 healthy individuals assayed using a similarly sensitive error-corrected sequencing method (Acuna-Hidalgo et al., 2017). Additionally, 39% of pre-AML cases over age 50 had a driver mutation with a VAF exceeding 10%, compared to only 4% of controls, a prevalence that is in line with the largest studies of CH-PD in the general population (Genovese et al., 2014) ( $P < 2.2 \times 10^{-16}$ , two-sided Fisher's exact test; Figure 3.1b). The median number of driver mutations per individual increased with age and was significantly higher in the pre-AML group relative to controls ( $P < 2.2 \times 10^{-16}$ , two-sided Wilcoxon rank-sum test; Figure 3.1c). Furthermore, examination of VAF distribution revealed significantly larger clones among the pre-AML cases ( $P = 1.2 \times 10^{-13}$ , two-sided Wilcoxon rank-sum test; Figure 3.1d).

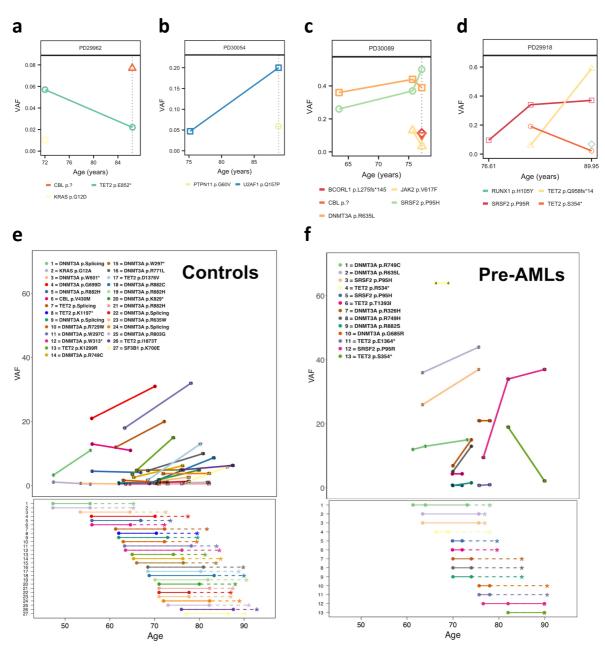

#### 2.2 Clonal dynamics over time and evolution to AML

In order to explore the mechanisms underpinning the higher mutation burden in pre-AMLs and the relationship between CH-PD and future leukaemia, I sequenced serially collected samples available for a subset of the VC (12 pre-AMLs and 141 controls) as well as three FFPE-fixed bone marrow biopsy samples available from AML diagnosis (PD29962, PD30054, PD30089). Comparison of the pre-AML mutations to the mutations detected in the diagnostic specimen demonstrated that most, though not all, drivers persisted and of these only a subset expanded to become clonal in the future AML (Figure 3.2a-c). The sensitivity of sequencing for the AML diagnostic samples was limited by the low quality of the FFPE-derived DNA and variable sequencing coverage. For PD29962, no putative drivers with VAF exceeding 9% were detected at diagnosis. In this individual, a clone harbouring a TET2 p.E852\* variant persisted for over 14 years, but decreased in size. A KRAS p.G12D variant also detected prediagnosis became undetectable, though with only 79 reads covering this locus in the diagnosis DNA, it is possible that it persisted at a subclonal level. Both PD30054 and PD30089 show evidence of persistent clones that became clonal in the AML, as well as new drivers present at diagnosis. PD30089 also developed a JAK2 p.V617F-mutated clone, which persisted but decreased in size. For an additional case (PD29918), a third blood sample was taken very close to AML diagnosis (~1 month prior), demonstrating an SRSF2 p.P95R mutation detected at all three time points (Figure 3.2d), which almost certainly contributed to the AML, while the second mutation detected (TET2 p.S354\*) persisted at declining VAF. Furthermore, data from individuals for whom blood sampling was done less than a year before AML diagnosis (n=9) show that the majority of these cases have driver mutations at high VAF (Figure 3.2e-f, Appendix 9), again suggesting that the pre-AML clones detected are likely to include those that later evolved into AML in most cases. Collectively these findings suggest that the driver mutations identified in pre-AML cases may represent a combination of pre-leukaemic clones as well as additional 'bystander' clones which do not transform. Several studies suggest that such independent clones may be common in AML patients at diagnosis (Parkin et al., 2017; Wong et al., 2015a). For example, a recent study of patients undergoing induction therapy found that five out of fifteen had marked expansion of clones unrelated to the founding AML clone but detectable in diagnostic specimens using error-corrected sequencing (Wong et al., 2015a).

**Figure 3.2 | Evolution of clonal haematopoiesis and relationship with future AML**. a-c, VAF trajectories of putative driver mutations in three individuals for whom bone marrow biopsy specimens taken at time of AML diagnosis (dashed black vertical line) were available for sequencing. Note that coverage for the diagnostic sample of PD30089 was insufficient to meaningfully compare the relative VAFs of the drivers in *DNMT3A* and *SRSF2*. **d**, VAF trajectories of driver mutations in an individual sampled three times, with last sample taken one month before AML diagnosis.

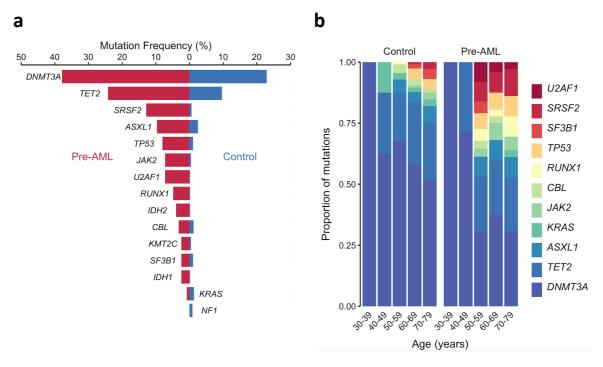

**e,f,** VAF trajectory of persistent clones carrying putative driver mutations in controls (**e**) and pre-AML cases (**f**). Upper plots: Circles denote individual serial samples and solid lines representing the growth trajectory between serial samples. Lower plots: dashed lines indicate the time interval between the last sampling and the end of follow-up (controls) or AML diagnosis (cases). Code for panels e and f by Dr Sagi Abelson. We sought to formally assess whether the clonal expansion rate was significantly different for the serial samples taken from controls versus pre-AMLs. However, this measurement is confounded by multiple factors, not least the inability to determine whether or not co-occurring mutations reside in the same clone. Hence, this experiment is inadequate to draw any conclusions. Studying the impact of mutation on AML development at the clonal level, for example by culturing and sequencing single-cell derived colonies, would help to address this question (Nangalia et al., 2019).

#### 2.3 The genetic landscape of pre-AML versus CH

In line with previous studies of CH in the general population (Jaiswal et al., 2014; Xie et al., 2014), DNMT3A and TET2 were the most commonly mutated genes in both groups (Figure 3.3a). No canonical NPM1 mutations nor any FLT3-internal tandem duplication mutations were detectable, consistent with these arising late in leukaemogenesis (Kronke et al., 2013; McKerrell et al., 2015). Recurrent CEBPA mutations, which are implicated in around 10% of *de novo* AML (Papaemmanuil et al., 2016), were also absent, suggesting that driver events in this gene may also be late events in *de novo* AML evolution, despite their involvement in familial AML. Notably, mutations in splicing factor genes (SF3B1, SRSF2 and U2AF1) were significantly enriched among the pre-AML cases relative to the controls (odds ratio, 17.5; 95% confidence interval, 8.1–40.4;  $P = 5.2 \times 10^{-16}$ , two-sided Fisher's exact test) and were present in significantly younger individuals (median age 60.3 compared to 77.3 years,  $P = 1.7 \times 10-4$ , two-sided Wilcoxon rank-sum test; Figure 3.3b). Screening all SNPs for potential pathogenic germline variants relevant to cancer or blood disorders (Methods section 3.4) identified only one likely pathogenic lesion, MPL p.Q186K (ClinVar accession RCV000015217.22). This SNP has been implicated in congenital amegakaryocytic thrombocytopenia (Ihara et al., 1999), though the participant carrying it (PD30060) had normal pre-diagnosis blood counts and developed AML aged 91.

#### 2.4 Genetic AML risk prediction model

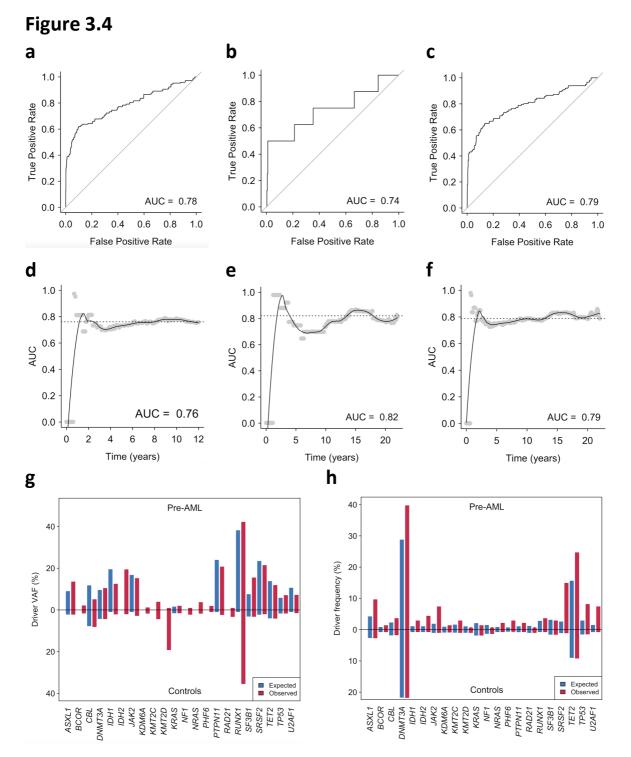

These findings demonstrate marked differences in both mutation burden and driver landscape between CH-PD observed in controls and pre-AML. Moreover, these results, in conjunction with recent insights into the origins of AML relapse (Shlush et al., 2017), suggests that AML progression typically occurs over many years through clonal evolution of preleukaemic haematopoietic stem and progenitor cells (HSPCs) before acquisition of late mutations leads to overt malignant transformation. In order to quantify the relative contributions of driver mutations and clone sizes to the risk of progressing to AML, we applied a Cox proportional hazards regression approach, which achieved similar performance in both the discovery cohort (concordance (C) =  $0.77 \pm 0.03$ ) and the validation cohort (C =  $0.84 \pm$ 0.05; Figure 3.4a-f and Table 3.1). A ridge regularised logistic regression model trained using the same variables produced very similar results (Table 3.2) As discussed in Methods section 4.1, we used weighting to minimise the biases introduced by the artificial case-control ratio (Antoniou et al., 2005; Therneau and Grambsch, 2000) and calculated hazard ratios relative to the (approximate) true cumulative incidence of about 1-3/1,000 in the given age range over a follow up of 10-20 years. The observed driver mutation frequency and VAF in premalignant samples closely resembled values expected based on the estimated risks, indicating that risk model and driver prevalence are well aligned (Figure 3.4g-h).

\*Derived from 100 bootstraps out-of-bag validation DC, discovery cohort; VC, validation cohort

Models that were only trained on data from the discovery or validation cohort had similar coefficients (Figure 3.5, Appendix 10). We therefore combined the datasets for a more accurate analysis of the contributions of mutations in individual genes to risk (C =  $0.77 \pm 0.05$ ; area under curve, 0.79; Figure 3.4c,f and Table 3.1).

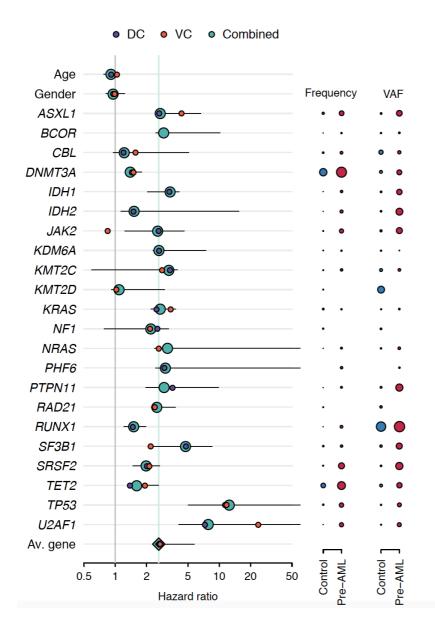

Quantitatively, we found that driver mutations in most genes conferred an approximately twofold increased risk of developing AML per 5% increase in clone size (Figure 3.5). Notable exceptions to this trend were the most frequently mutated CH genes, *DNMT3A* and *TET2*, which conferred a relatively lower risk of progression to AML (Figure 3.5, Fig 3.6a,c,e). By contrast, a larger effect size was apparent for *TP53* (hazard ratio, 12.5; 95% confidence interval, 5.0–160.5) and *U2AF1* (hazard ratio, 7.9; 95% confidence interval, 4.1–192.2) mutations (Figure 3.5, Figure 3.6a,b,d). However, other CH-PD genes, such as *SRSF2*, contributed a similar relative risk owing to their presence at a higher VAF in pre-AML cases (Figure 3.5, Figure 3.6a). Because the effect of each driver mutation is deleterious and the effect of multiple mutations that are present in the same individual is multiplicative, a higher number of mutations is predicted to increase the risk of progression to AML (Figure 3.7a). Similarly, the size of the largest driver clone was also strongly associated with the risk of progression to AML, in agreement with the risk of individual mutations generally being proportional to VAF (Figure 3.7b).

Estimates of model sensitivity and specificity necessitate arbitrary age-cut-offs which dramatically impact the interpretation of predictions. Is it most relevant to know whether or not an individual will develop AML before age 100 or before age 60 and which estimate should sensitivity/specificity be determined for? The Cox proportional hazards model illustrated in

figure 3.5 facilitate a more tangible interpretation of excess risk on an individual level, harnessing the genomic snapshot from a blood sample to estimate the risk of developing AML over the next 10 years in a manner which accounts both for a person's age and the incidence of AML in their given age bracket.

Comparing AML risk prediction models based on the VAF of mutations in individual genes versus mutation burden alone demonstrated that the gene-level model performed best (Figure 3.7c,d). Concordance and AUC were both 3-4% improved for the models incorporating gene-level risk, which is a considerable margin, particularly for a rare disease. Moreover, the disparities in gene-level hazard ratios (HR) were significant (Figure 3.5), despite the fact that the genes with the highest HR are not mutated frequently enough to have a very dramatic effect on overall model AUC. Collectively, although the VAF and the number of mutations confer much of the predictive value, the gene-level analysis (Figure 3.5) does demonstrate distinct gene-level risks, and is able to quantify the cumulative impact of multiple mutations and clonal size on the likelihood of progression to AML. Furthermore, in order to examine whether the genetic model can distinguish between CH-PD and pre-AML even when individuals without mutations were excluded, we retrained the model using only cases and controls with CH-PD. We found that performance was if anything marginally improved by this manoeuvre (Concordance > 0.8 on both discovery and validation cohorts, Appendix 7).

## Figure 3.5

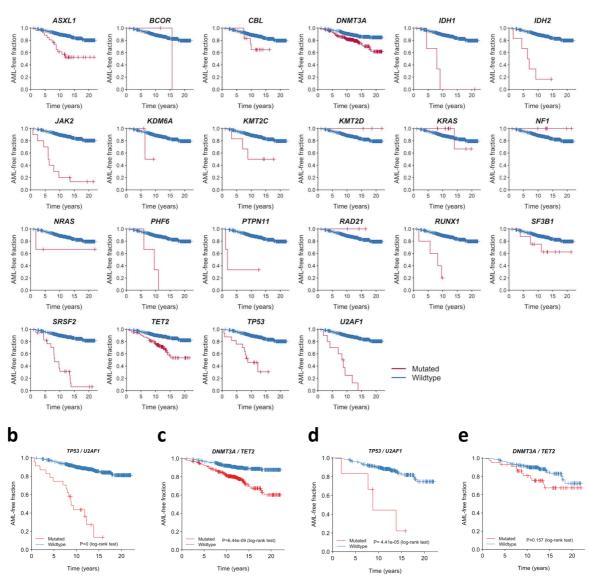

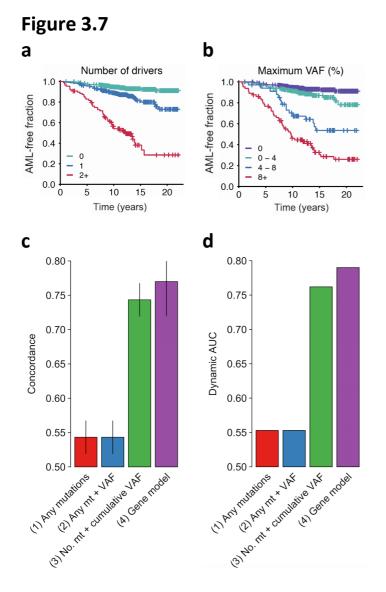

Purple, orange and green circles indicate hazard ratios (HR) for the discovery (DC), validation (VC) and combined cohort, respectively. Horizontal lines denote 95% confidence intervals for the combined cohort. For each gene, the indicated HR applies to the 10-year risk of AML conferred by each 5% increase in mutation VAF. The green vertical line indicates the mean HR across all genes. The HR for *RUNX1* must be interpreted with caution owing to the relatively high prevalence of deleterious germline variants in this gene, which may not be readily distinguishable from somatic mutations in unmatched sequencing assays. The proportion of individuals with mutations in each gene and the average VAF are indicated to the right of the forest plot.

a-b, Kaplan–Meier curves of AML-free survival, defined as the time between sample collection and AML diagnosis, death or last follow-up. Survival curves are stratified according to number of driver mutations per individual (a) and largest clone detected (**b**). VAF bins of 4% are shown in (b) to illustrate the consistency of the trend towards lower AMLfree survival with larger clone size. c, Leave-one-out crossvalidated concordance C of different risk models based on (1) the presence of any mutation, (2) the presenced of any mutation and the cumulative VAF of different clones, (3) the number of different driver mutations and cumulative VAF as predictors and (4) a model incorporating the effects of individual genes. d, Same models as in (c), but using Uno's dynamic AUC as a measure of model performance. VAF, variant allele fraction; mt, mutation; No. mt, number of mutations; AUC, area under the curve.

#### 2.5 Clinical factors associated with AML risk

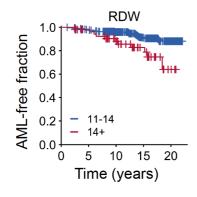

Although genetic features alone are capable of identifying many individuals at risk of developing AML in these experimental cohorts, AML incidence rates in the general population are low (4:100,000) (Deschler and Lubbert, 2006), and thus millions of individuals would need to be screened to identify the few pre-AML cases, with many false positives. To determine whether routinely available clinical information could improve prediction accuracy or identify a high-risk population for targeted genetic screening, I initially reviewed full blood count and biochemistry data that were available for 37 of the pre-AML cases and 262 controls. These data also permitted a screen for any potentially undiagnosed cases of MDS, a known risk factor for (secondary) AML (Arber et al., 2016). The diagnosis of MDS based on the WHO criteria relies not only on the presence of dysplasia in at least one lineage, but also on the presence of at least one significant cytopenia (haemoglobin (Hb) <10g/dL; platelet count<100 x10<sup>9</sup>/L and absolute neutrophil count<1.8 x 10<sup>9</sup>/L)(Arber et al., 2016). The latest WHO criteria state verbatim that "Cytopenia is a 'sine qua non' for any MDS diagnosis...", hence enabling exclusion of MDS based on normal blood counts alone (Arber et al., 2016). Out of the 37 pre-AMLs only one had Hb<10g/dL at recruitment (PD30116, Hb 9.8g/dL); however, three years later Hb had normalised to 13.7g/dL, thus excluding MDS. The only other cytopenia in a pre-AML was a sample with platelets of  $91 \times 10^9$ /L at baseline (PD30010); however, 3.7 years later the platelet count had risen above the WHO guideline threshold (106 x 10<sup>9</sup>/L), suggesting that MDS was not the diagnosis. CH-PD was also overwhelmingly associated with normal blood counts in the controls, even in individuals harbouring multiple mutations at high VAF (e.g., PD35659c, PD35733b and PD35788b with leukaemia-free follow-up of 20.3, 20.4 and 17 years, respectively). The presence of normal blood counts in association with large clones corroborates the findings of previous studies of CH in the general population (Buscarlet et al., 2017; Jaiswal et al., 2014; McKerrell et al., 2015). Overall, full blood count data between controls and pre-AMLs did not differ, with the notable exception of red cell distribution width (RDW) (Figure 3.8a,b) Despite the limited sample size, there was a significant association between higher RDW and risk of progression to AML (P = 0.0016, Wald test with Bonferroni multiple-testing correction). Although traditionally used in the evaluation of anaemias, raised RDW has been correlated with inflammation, ineffective erythropoiesis, CVD and adverse outcomes in several inflammatory and malignant conditions (Hu et al., 2017). The correlation

between RDW and risk of AML development remained highly significant when only controls with CH-PD were compared to pre-AMLs (P =  $3.5 \times 10^{-6}$ , Wald test with Bonferroni multiple testing correction). Higher RDW has previously been associated with CH and overall mortality (Jaiswal et al., 2014; Salvagno et al., 2015), but has never been shown to distinguish CH from pre-leukaemia.

Figure 3.8

b

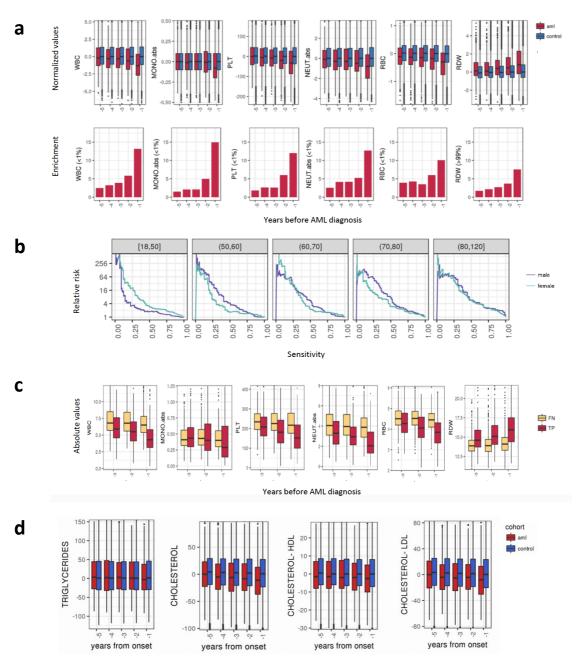

**Figure 3.8 | Full blood count indices in pre-AMLs and controls. a**, Box plots of full blood count parameters. Box plot centres, hinges and whiskers represent the median, first and third quartiles and 1.5× interquartile range, respectively. **b**, Kaplan–Meier curves of AML-free survival, defined as the time between sample collection and AML diagnosis, death or last follow-up. Survival curve is stratified according to RDW measurement data for n = 299 unique individuals for whom full blood count measurements were available. Among the blood indices shown, only RDW was significantly different between pre-AML cases and controls (P = 0.0016, Wald test with Bonferroni multiple-testing correction).

In order to verify RDW as a predictive factor and determine whether additional clinical parameters are associated with risk of AML development, we collaborated with Dr Netta Mendelson Cohen, Dr Elisabeth Niemeyer and Dr Noam Barda, who analysed the Clalit electronic health record (EHR) database (Balicer and Afek, 2017). This resource contains EHRs for an average of 3.45 million individuals per year collected over a 15-year period. Stringent criteria based on diagnostic codes and treatment records identified 875 AML cases (Appendix 11). Consistent with case ascertainment strategy for the genetic model, all cases of secondary AML following another myeloid malignancy were excluded. Analysis of RDW trends revealed significantly raised measurements several years before AML diagnosis relative to age and sexmatched controls (Figure 3.9a). The most pronounced increase in RDW was observed at 6-12 months before diagnosis, with ~10% of pre-AMLs having RDW values which were greater than the 99th centile of the controls. Many other blood indices, including several full blood count (FBC) parameters, changed six months to a year before diagnosis. Additional parameters that correlated with risk of AML development included reductions in monocyte, platelet, red blood cell and white blood cell counts (Figure 3.9a). However, in the majority of cases measurements did not fall outside the normal reference ranges. Nevertheless, these values were statistically distinct from those seen in large numbers of age and sex-matched controls. This is important, as it shows that these individuals did not have undiagnosed MDS/MPN, and suggests instead that evolving *de novo* AML may sometimes have a considerable prodrome with subtle but discernible clinical manifestations, potentially reflecting large pre-leukaemic clones.

Our collaborators next applied a machine-learning approach to construct an AML prediction model based entirely on variables that are routinely documented in electronic health records (Appendix 11). This model predicted AML 6–12 months before diagnosis with a sensitivity of 25.7% and overall specificity of 98.2%. The model performed consistently across different age groups with an increased relative risk of 28 for males and 24 for females between the age of 60 and 70 years (Figure 3.9b). To our knowledge this represents the first analysis of its kind in AML prediction from routinely collected clinical records. In order to better understand which patients are most likely to be accurately classified by this model, our collaborators compared absolute laboratory values for true positives and false negatives. This revealed that 35.5% of false-negative predictions were for patients for whom infrequent blood count data were available. Some of the true-positive cases had mildly abnormal blood

counts that would not initiate a diagnostic work-up (Figure 3.9c), whilst cytopenias that would be compatible with undiagnosed myelodysplastic syndrome (Arber et al., 2016) were uncommon. Other non-haematological variables associated with progression to AML included higher triglyceride levels and lower high- and low-density lipoprotein levels (Figure 3.9d).

#### Figure 3.9

**Figure 3.9 | Increased risk of AML development inferred from electronic health records. a**, Box plots of normalized laboratory measurements. Increased RDW, reduction in monocyte, platelet, red blood cell (RBC) and white blood cell (WBC) counts (top) show a high association (bottom) with a higher risk of AML development and differed at least a year before AML diagnosis. **b**, Model performance stratification by age and gender. Age ranges are indicated above each graph. **c**, Absolute laboratory values for true positive (TP) and false negative (FN) predictions. **d**, Box plots of lipid levels. Box plots indicate median, first and third quartiles and 1.5× interquartile range. WBC, white blood cell count; MONO.abs, absolute monocyte count; PLT, platelet; NEUT, neutrophil; RBC, red blood cell; RDW, red cell distribution width; FN, false positive; TP, true positive; AML, acute myeloid leukaemia; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

#### 3. Discussion

This study sought to explore the natural history and genetic landscape of nascent AML and the extent to which the latter is distinct from CH in the general population. Collectively, these findings provide new insights into the pre-clinical evolution of AML and the feasibility of identifying CH at high risk of malignant transformation.

#### 3.1 A long latency period is the rule rather than the exception in AML

This work demonstrates for the first time that pre-leukaemic clones can be detected in the majority of individuals who develop AML 6 or more years before clinical disease manifestations, even when interrogating for point mutations alone. This long latency has now also been reported by Desai et al, who performed a very similar nested case-control study (Desai et al., 2018). Desai and colleagues sequenced 67 AML-associated genes in peripheral blood samples from 212 women diagnosed with AML a median of 9.6 years later alongside the same number of controls (Desai et al., 2018). Consistent with our results, pre-leukaemic clones (VAF>1%) were present in 68.6% and 30.9% of pre-AML cases and controls, respectively (Desai et al., 2018). This long pre-clinical evolution highlights important aspects of AML biology and reveals that the window for potential intervention is measured in years for the majority of individuals who develop AML.

#### 3.2 The distinct driver landscape of pre-AML

This work also reveals that the mutational landscape, and not simply the mutation burden, differs between CH in controls versus pre-AML. The differences in the mutational spectrum observed between pre-AML cases and controls may arise through cell-intrinsic or extrinsic factors. As discussed in Chapter 1, previous studies of clonal haematopoiesis have demonstrated that clones with particular mutations dominate in the context of specific environmental pressures (Gibson et al., 2017; Hsu et al., 2018; McKerrell et al., 2015; Takahashi et al., 2017; Wong et al., 2015b), suggesting an important role for cell-extrinsic factors in haematopoietic somatic evolution. Although such factors in CH remain poorly understood, it is intriguing that mutations in splicing factor genes and *TP53* were significantly enriched among the pre-AMLs relative to the controls, with the former presenting in significantly younger individuals than in benign CH. Spliceosome mutations appear to confer a competitive advantage in the context of ageing, and were almost exclusively observed in the general population in individuals over age 70 years (McKerrell et al., 2015). Similarly, clones harbouring *TP53* mutations expand dramatically with exposure to intensive chemoand/or radiotherapy (Bondar and Medzhitov, 2010; Wong et al., 2015b). However, *TP53*mutated HSC clones are very common at extremely low VAF in the elderly, but tend to remain stable in size over time, suggesting only a modest selective advantage in the absence of increased genotoxic stress (Wong et al., 2015b). Therefore, it is possible that the significantly higher prevalence of clones with *TP53* and spliceosome gene mutations in pre-AML cases may reflect distinct microenvironmental selection pressures rather than earlier mutation acquisition.

#### 3.3 The significance of the higher mutation burden in pre-AML

The observation of the higher burden of putatively oncogenic mutations (driver mutations) in the pre-AML cases across all age groups raised two main related questions. Firstly, what is the mechanism underpinning the discrepancy in mutation burden between controls and pre-AMLs? Secondly, do driver mutations detected in pre-AML cases reflect the presence of an AML ancestor, or do these mutations behave as surrogate markers of factors predisposing to leukaemogenesis?

Although speculative, several mechanisms may account for the higher mutation burden and clone size observed in the pre-AMLs. It could reflect a higher mutation rate in the pre-AML cases, for example due to higher HSC turnover, potentially secondary to depletion of the functional HSC pool. Alternatively, chance may play a dominant role, with stochastic driver mutation acquisition triggering clonal expansion, thus increasing the odds of further driver events on a pre-malignant background leading to selection for progressively more mutated clones. However, this multistage cancer evolution paradigm does not account for the relationship between the fitness advantage conferred by a driver mutation and the environmental context of the mutated cell (Rozhok et al., 2014). Clones with drivers could be under stronger selective pressure in certain bone marrow environments, as is seen in particular clinical contexts such as aplastic anaemia or after intensive cytotoxic therapy (Hsu et al., 2018; Wong et al., 2015b; Yoshizato et al., 2015). As discussed in the introduction, the presence of selective pressure favouring clonal expansions, rather than mutation acquisition, may thus be an important determinant of the number of mutations detectable by bulk sample sequencing.

Our time series experiment and sequencing of diagnostic specimens helped partially address the second question, demonstrating that clones in pre-AML cases represent a combination of leukaemia ancestors and 'bystander' clones that likely are not related to the future AML. However, our experiment using bulk cell populations was too small and hindered by confounding factors to enable strong conclusions about clonal growth kinetics or mutation rates. We hope that future experiments using single cell and/or highly purified cell population studies on viable cells at serial time points will shed light on these questions.

#### 3.4 Rationale for AML risk prediction and future directions

Cancer predictive models have enabled successful early detection and intervention programmes for several solid tumours (Vickers, 2011; Wang et al., 2014). However, screening tests are unavailable for the sub-clinical stages of most haematological malignancies. Given that the main cause of mortality in AML is treatment resistance/relapse (Döhner et al., 2015), there is a rationale for identifying and treating a genomically simpler antecedent of the disease. In this context, reduction of clonal size rather than complete clonal extinction may be sufficient to significantly reduce the risk or slow AML progression. Such an approach has proven very effective in CML, which has been transformed by targeted therapy into a chronic condition with a dramatically reduced incidence of progression to CML blast crisis (Kalmanti et al., 2015). Furthermore, CH is associated with and may play a causal role in common nonmalignant conditions (Fuster et al., 2017; Jaiswal et al., 2017), which may strengthen the case for screening and intervention.

#### *3.4.1 Further development of genetic AML prediction methods*

This study provides proof-of-concept for the feasibility of early detection of healthy individuals at high risk of developing AML. The models presented here demonstrate that somatic genetic features are predictive of AML progression and that the presence of mutations in certain genes confers a greater risk. Desai et al have since identified similar gene-level risk factors (Desai et al., 2018). Consistent with our results, *TP53* mutations conferred the highest odds ratio of progression from CH to AML, followed by drivers in *IDH1/2* and

spliceosome genes (Desai et al., 2018). Although Kaplan-Meier analysis (Figure 3.6) is consistent with a trend towards shorter AML-free survival with *IDH1/2* mutations, we chose not to group functionally-related genes in our analysis in order to reach significance, as their mechanistic consequences may differ (e.g., *IDH2* p.R140 and *IDH2* p.R172 (Papaemmanuil et al., 2016)). In addition to improving model performance, the identification of highly significant disparities in gene-level HR offers compelling biological insights into the determinants of clonal progression, which warrant further investigation.

Given that most of the genetic model's predictive power stems from mutations with VAFs >0.005, our data suggests that conventional deep targeted sequencing, as used for the validation cohort, is adequate for future screens when combined with stringent variant calling and driver mutation curation. Thus, the additional cost of error correcting sequencing is unlikely to be justified. However, it is possible that future studies may show that specific mutations may have predictive value when detected accurately even at low VAF (e.g. *U2AF1* hotspot variants).

As recurrent chromosomal translocations are likely to be initiating events in approximately 20% of AML (Papaemmanuil et al., 2016), incorporating these into the genetic model is likely to further increase predictive accuracy. McKerrell et al. have shown that it is feasible to simultaneously capture several recurrent translocations/inversions with targeted panels only slightly larger than the ones used in the current study (McKerrell et al., 2016). Additionally, expanding this dataset will make it possible to investigate whether co-mutation patterns carry prognostic significance, as is the case in AML (Gerstung et al., 2017; Papaemmanuil et al., 2016).

#### 3.4.2 Combining clinical and genetic information to risk-stratify clonal haematopoiesis

The predictive model based on mutations and demographic features partially overcomes the limitations imposed by the low overall incidence of AML, but does not eliminate them. We have shown that commonly recorded clinical parameters, notably RDW and other FBC indices, may identify a smaller population with higher pre-test AML risk for screening. Although clinical parameters were predictive relatively close to the time of AML diagnosis, pre-AML clones can be of significant size many years before diagnosis and it is entirely plausible that surrogate laboratory markers of their presence may be identifiable much earlier, as we found for RDW in the validation cohort. Analysis of the 37 individuals for whom both genomic and clinical information were available found that 6% of the relative risk contribution was attributable to clinical variables, suggesting that combining routinely available clinical data with genomic variables may strengthen AML prediction models. Extending this analysis in a large EHR database further revealed that pre-AML has additional subtle clinical manifestations which in themselves had considerable predictive power 6-12 months prior AML diagnosis. This further supports a role for clinical variables in strengthening genomic prediction models and/or in targeting the population most likely to benefit from screening for CH.

Defining the population most likely to benefit from genetic screening will also depend on improved understanding of the role of CH in common non-malignant conditions. If, as several recent studies strongly suggest, some pre-leukaemic clones are pro-inflammatory and actively promote atherosclerosis and cerebro/cardiovascular adverse events (Fuster et al., 2017; Jaiswal et al., 2017), then a significantly larger proportion of the population might benefit from screening for CH and could thus be considered for possible interventions to suppress pre-leukaemic clones and/or mitigate established cardiovascular risk factors (blood pressure, dyslipidaemia, etc). Our analysis of a large EHR database reveals that subtle clinical manifestations, including trends in triglycerides and RDW that are established risk factors for cardio/cerebrovascular disease also correlated with risk of AML. It is conceivable that there are unifying characteristics of high-risk CH emblematic of the emerging links between ageing and dysregulated inflammation or immune senescence (Green et al., 2011; Shaw et al., 2013).

Clearly these findings cannot address the challenging question of how genomic screening methods should be implemented in a real-world setting, and a combined clinical and genetic screening approach requires validation in large prospective cohort studies. Promisingly, the infrastructure for performing such studies is increasingly available, for example the UK Biobank (Bycroft et al., 2018). These resources should help stimulate large prospective studies that take account of all health outcomes associated with CH.

### Chapter 4

# The pre-clinical evolution of lymphoid neoplasms

#### 1. Introduction

As discussed in Chapter 1, the initial exome-based screens for CH in the general population established that most somatic mutations occur in a limited number of genes most frequently implicated in myeloid neoplasms (Genovese et al., 2014; Jaiswal et al., 2014; Xie et al., 2014). However, two of these studies screened broadly for candidate driver events and revealed a broader mutational spectrum, including rare oncogenic mutations in several genes closely associated with lymphoid malignancies, such as *ATM*, *CREBBP* and *MYD88* (Genovese et al., 2014; Xie et al., 2014). The majority of the sensitive, targeted surveys of CH-PD in the general population have since been biased towards detecting mutations in myeloid cancer genes (Acuna-Hidalgo et al., 2017; Coombs et al., 2017; McKerrell et al., 2015; Young et al., 2016). Collectively, these studies have yielded several important insights into CH that were inaccessible to the initial exome screens, for example the high prevalence of small clones harbouring spliceosome gene mutations in older individuals (discussed in Chapter 1, section 3.4.1)(McKerrell et al., 2015; McKerrell and Vassiliou, 2015). Although there is considerable overlap between the cancer genes involved in the commonest lymphoid and myeloid malignancies, the former are generally characterised by more diverse genetic landscapes,

with a significant proportion of driver events occurring in infrequently mutated cancer genes (Bolli et al., 2014; Landau et al., 2015; Landau and Wu, 2013; Reddy et al., 2017; Sabarinathan et al., 2017). Given the current literature on CH, it is unclear whether or not a similar spectrum of mutations affecting these less recurrent cancer genes is mirrored in the general ageing population at very low VAF. This is relevant to understanding the selective pressures operative in the ageing haematopoietic niche and to understanding the relationship between CH-PD and lymphoid neoplasms.

As discussed in the introduction to Chapter 3, the studies reporting an association between CH and haematological malignancies were not powered to study distinct classes of blood cancer (Genovese et al., 2014; Jaiswal et al., 2014). The work described in Chapter 3 delineates notable differences in the prevalence and mutational landscape of CH-PD in individuals who later develop *de novo* AML versus that seen in controls, and demonstrates that these genetic features have predictive value for future AML development. However, the extent to which the same is true for other blood cancers remains poorly understood.

The work described in this chapter aims to explore this question by undertaking a broader survey of candidate CH-PD driver genes (Appendix 6) in a cohort of individuals later diagnosed with a lymphoid neoplasm and healthy controls, using a nested case-control experimental design similar to that described in Chapter 3 for AML.

#### Aims:

- Compare the prevalence and mutational landscape of CH-PD in the general population with that observed in individuals who go on to develop a lymphoid neoplasm.
- Correlate genetic features and routinely collected clinical variables with risk of progression to lymphoid malignancy
- 3) Investigate the combined predictive power of genetic, clinical and demographic features to identify individuals at high risk of developing a lymphoid neoplasm.

#### 2. Results

#### 2.1 Cohort overview

Our EPIC-Norfolk (Day et al., 1999) collaborators (Nick Wareham, Robert Luben, Shabina Hayat and Abigail Britten) identified a discovery cohort comprising 118 study participants diagnosed with a lymphoid neoplasm a mean of 8.0 years (IQR 4.3 - 11.1) after peripheral blood sampling and 118 age- and sex-matched controls with no record of any cancer or haematological disorder (Appendix 12). Individuals were excluded if they were sampled less than 6 months before diagnosis or had a lymphocyte count of 5 x 10<sup>9</sup>/L or above, which might be high enough to trigger a clinical work-up for monoclonal B-cell lymphocytosis (MBL) according to current diagnostic criteria (Swerdlow et al., 2016). Given that MBL is a known risk factor for chronic lymphocytic leukaemia (Strati and Shanafelt, 2015), the commonest chronic leukaemia in adults (Dores et al., 2007), we focussed on individuals with lymphocyte counts that would not, in isolation, elicit clinical suspicion of an underlying neoplasm (Swerdlow et al., 2016). The mean age at blood sampling for discovery cohort cases was 64.6 years (IQR 57.0 - 71.8). A validation cohort was also sourced from EPIC-Norfolk and included 71 pre-lymphoid neoplasm (pre-LN) cases and 71 controls (Appendix 13). The mean interval between blood sampling and diagnosis for the validation cohort cases was 8.4 years (IQR 4.1 - 12.3) and mean age at sampling was 64.0 years (IQR 59.4 - 69.8). For the controls, the mean duration of follow-up was 15.4 and 16.4 years for the discovery and validation cohorts, respectively. Serial premalignant samples were available for a subset of the discovery cohort cases and controls. Clinical metadata including full blood count, lipid profile, blood pressure and anthropomorphic measurements were available for the majority of cases and controls. Moreover, out of the 262 controls with clinical metadata described in Chapter 3, 189 were adequately age-and sex-matched to the pre-LN cases, providing a case:control ratio of 1:2 for analysis of clinical factors associated with progression to lymphoid malignancy. These controls were also used to compare mutation frequency in genes that overlapped across the gene panels (Appendices 4 and 6).

The spectrum of future LN diagnoses was similar between the discovery and validation cohorts and is summarised in Table 4.1 with complete metadata for both cohorts detailed in Appendices 12 and 13. For many cases, particularly individuals later diagnosed with a non-

86

Hodgkin lymphoma, histopathological subtype is unknown. Furthermore, disease classification schemes have evolved dramatically over the course of the recruitment period (Campo et al., 2011; Chapuy et al., 2018; Swerdlow et al., 2016), which would complicate translating historical diagnoses into currently recognised disease entities, and is not essential for the aforementioned aims of this study.

Diagnosis	Diagnosis abbreviation	Number of individuals	Mean interval between sample and diagnosis (years)	Mean age at sampling (years)
Peripheral T-cell lymphoma NOS	PTCL NOS	6	8	65.0
Mycosis fungoides	MF	1	3.1	69.9
Non-Hodgkin lymphoma NOS	NHL NOS	37	6.5	65.2
Acute lymphoblastic leukemia	ALL	1	13.3	50.2
Lymphoblastic lymphoma	LL	1	18.5	60.0
Multiple myeloma	MM	43	7.9	63.7
B-cell non-Hodgkin lymphoma	B-NHL	26	7.2	63.2
Diffuse large B-cell lymphoma	DLBCL	25	10.9	64.5
Chronic lymphocytic leukemia	CLL	20	9.1	67.3
Monoclonal gammopathy of undetermined significance	MGUS	12	8.2	65.3
Hodgkin lymphoma	HL NOS	4	14.1	56.1
Small cell B-cell lymphoma	SLL	4	8.4	61.5
Waldenstrom macroglobulinaemia	WM	3	3.9	67.9
Hairy-cell leukemia	HCL	2	4.8	72.8
Nodular sclerosis Hodgkin lymphoma	NScHL	2	5.1	61.3
Extramedullary plasmacytoma	EP	2	6.4	64.2

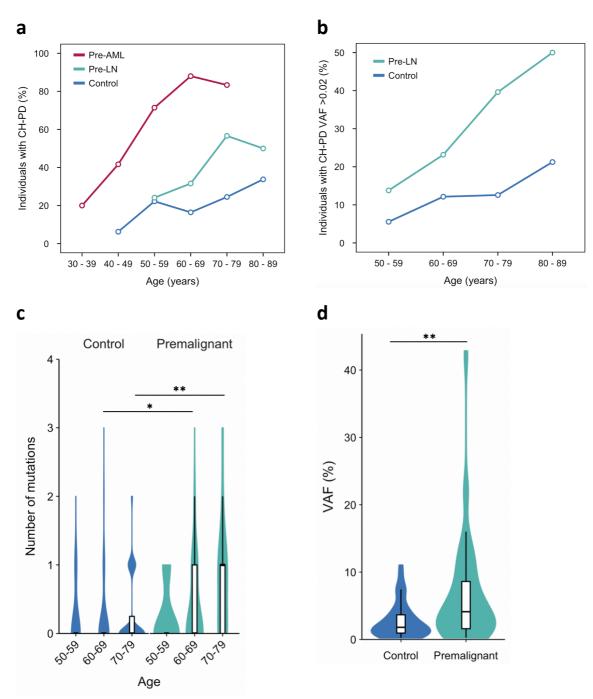

#### Table 4.1 | Pre-LN cohort summary

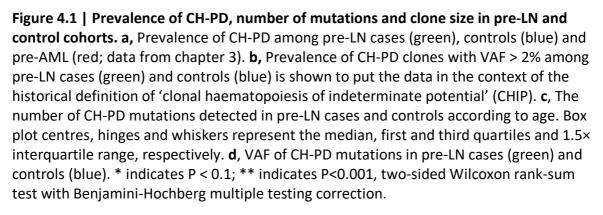

#### 2.2 Prevalence of CH-PD and driver mutation burden

Peripheral blood samples were deep sequenced with a custom panel comprising 95 genes implicated in haematological malignancies (Methods section 2.4 and Appendix 6). Average sequencing coverage was >5,000 (IQR 4,750 – 5,800). The prevalence of CH-PD was significantly higher in pre-LN cases than in controls (P = 0.0019, two-sided Fisher's exact test), though the difference was less dramatic than that observed for pre-AML (Figure 4.1a). Overall the prevalence of CH-PD in pre-LN cases and controls was 35.4% and 20.6%, respectively (Figure 4.1a,b). These proportions were similar across the discovery cohort (CH-PD prevalence of 33.9% in cases and 17.8% in controls) and validation cohort (38% and 25.4% for cases and controls, respectively). The average number of driver mutations identified in pre-LN cases was 0.43 compared to 0.25 for controls (P=0.0016, two-sided Wilcoxon rank-sum test), with a

significant trend towards increasing driver mutation burden with age (Figure 4.1c). Moreover, as seen for pre-AMLs, the VAF of driver mutations was significantly higher in pre-LN cases versus controls (median VAF 6.9% and 2.8%, respectively; P = 0.00036, Wilcoxon rank-sum test; Figure 4.1d).

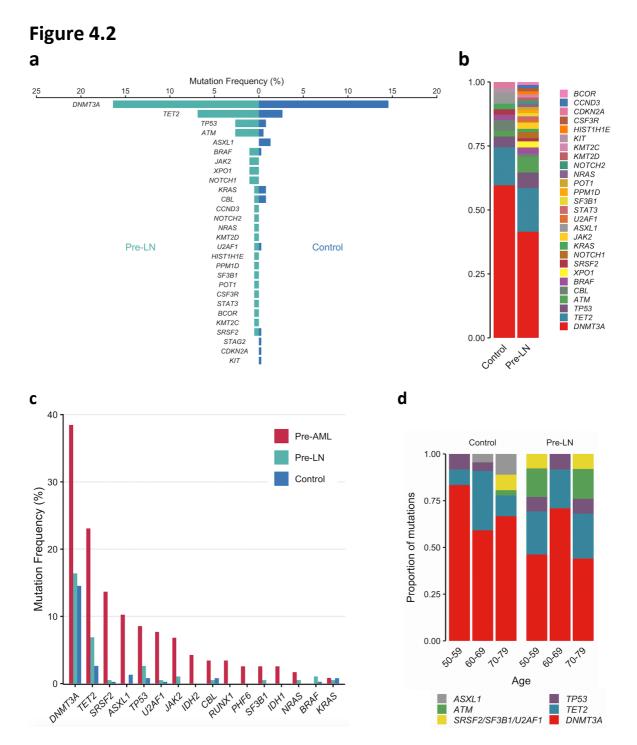

## 2.3 Mutational spectrum of CH-PD in individuals who later developed a lymphoid neoplasm

Among the 189 discovery and validation cohort controls, the top three most frequently mutated genes were DNMT3A, TET2 and ASXL1 (Figure 4.2a-c, Appendix 14), consistent with the findings of other studies of CH-PD in the general population (Bowman et al., 2018). By contrast, among individuals who later developed a lymphoid blood cancer, the most recurrently mutated genes were DNMT3A (16.4% of cases versus 14.4% of controls), TET2 (6.9% of cases vs 2.7% of controls), ATM (2.7% of cases vs 0.53% of controls) and TP53 (2.7% of cases and 1.1% of controls). Among the genes recurrently mutated in both cases and controls, the mean mutation VAF was consistently higher in cases, though this difference only reached statistical significance on an individual gene level for DNMT3A (mean VAF in cases and controls 5.9% and 2.8%, respectively; P = 0.029, two-sided Wilcoxon rank-sum test with BH multiple testing correction). Furthermore, CH-PD in the pre-LN cases demonstrated a remarkably diverse spectrum of mutations, with putative driver variants identified in a total of 24 genes, compared to 11 genes among the controls (Figure 4.2a,b). Although there is broad overlap between the cancer genes implicated in myeloid and lymphoid malignancies (Arber et al., 2016; Sabarinathan et al., 2017; Swerdlow et al., 2016), several of the genes mutated among the cases are predominantly implicated in the latter, including POT1, XPO1, HIST1H1E, NOTCH1, NOTCH2, ATM and CCND3 (Arber et al., 2016; Hing et al., 2016; Lunning and Green, 2015; Sabarinathan et al., 2017; Swerdlow et al., 2016).

Although data were too sparse to discern significant changes in the mutational spectrum with age, it is noteworthy that mutations in spliceosome genes (*SF3B1, SRSF2* and *U2AF1*) were only observed in controls over the age of 70, consistent with previous studies strongly associating these mutations with CH-PD in older individuals (Figure 4.2d)(McKerrell et al., 2015). Among the cases, the splicing gene mutation with the highest VAF (*SF3B1* p. K700E, VAF 2.1%) occurred in a 54-year-old man (PD00315) sampled 8 years before diagnosis with chronic lymphocytic leukaemia (CLL).

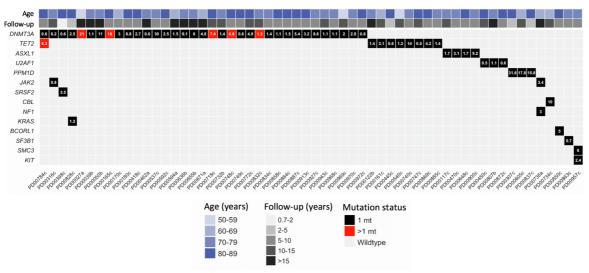

**Figure 4.2 | The mutational spectrum of clonal haematopoiesis in individuals who developed a lymphoid neoplasm years later versus controls. a,** Proportion of pre-LN cases (green) and controls (blue) with driver mutations each given gene. **b**, Relative frequency of mutations in the indicated genes according to age group for pre-LN cases and controls. **c**, Proportion of pre-AML (red), pre-LN (green) and control (blue) individuals with driver mutations in genes sequenced for both the pre-AML (chapter 3) and pre-LN cohorts. **d**, Relative frequency of mutations in the indicated at least 5 times included in panel, with spliceosome genes *SRSF2*, *SF3B1* and *U2AF1* aggregated.

## 2.4 Mutational spectrum in an extension cohort of older individuals with no record of cancer or a blood disorder

The more diverse genetic landscape of CH-PD in the pre-LN cases is intriguing, though the limited sample sizes and 1:1 case:control ratio warrant cautious interpretation. Although collectively a significant proportion of the mutations observed in the pre-LN cases occur in genes never or rarely reported in CH-PD in the general population, individual genes were infrequently mutated. Hence, despite the notable differences in mutational spectra between pre-LN cases and controls, considering all genes mutated more than 5 times across both cohorts on an individual basis, only TET2 mutations approached significance for enrichment among the pre-LN cases (6.9% vs 2.7% mutated) (P = 0.05, one-sided Fisher's exact test with BH multiple testing correction). Is the absence of recurrent LN-drivers in the 189 age-and sexmatched controls included in the discovery and validation cohorts truly representative of the frequency of such mutations in the general ageing population? As mentioned in the introduction, most of the sensitive targeted surveys of CH-PD have used gene panels restricted to the most recurrent CH-PD driver genes and have not included the aforementioned LN-associated cancer genes (Acuna-Hidalgo et al., 2017; Coombs et al., 2017; Gibson et al., 2017; McKerrell et al., 2017; McKerrell et al., 2015; Young et al., 2016). The cumulative incidence of both common adult lymphoid malignancies and of CH-PD increases dramatically with age (Howlader et al., 2011), and it is conceivable that a more diverse CH-PD genetic landscape enriched for recurrent LN drivers emerges at higher rates in older age groups, analogous to the trend observed for spliceosome gene mutations (McKerrell et al., 2015). To investigate this possibility, we sequenced an extension cohort of 234 individuals (n=238 samples) with no record of any prior or subsequent cancer diagnosis or known blood disorder. The mean age at blood sampling was 74.4 years (IQR 67.5-81.6), more than ten years older on average than the control cohort. The mean follow-up was 11.9 years (IQR 8.0-16.4). Out of the 234 individuals, 58 (24.8%) had CH-PD (Appendix 14). Despite high coverage (median >5,000X) and sensitivity to detect small clones down to VAF 0.5%, the genetic landscape was consistent with that observed in previous studies of CH-PD in the general ageing population. In particular, no canonical drivers associated with lymphoid malignancies were identified (Figure 4.3a,b), in contrast to the pre-LN cohort.

#### Figure 4.3

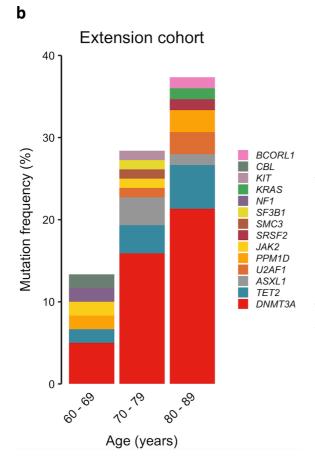

Figure 4.3 | The mutational spectrum of clonal haematopoiesis in an extension control cohort of older individuals with no history of cancer or haematological disorder. a, Co-mutation plot including only individuals with CH-PD (58 out of 234 individuals in the older extension cohort). The top two rows indicate age at sampling and follow-up period in years. Tiles are coloured according to mutation status for each given gene and number of drivers identified: pale grey, wild type; black, one driver mutation; red, two driver mutations. The mutation VAF (%) is indicated in white text within each tile. Where two mutations were identified in a given gene and sample (red tiles), the highest VAF is shown. b, Proportion of individuals with driver mutations in each given gene according to age group.

#### 2.5 Clonal dynamics over time and relationship with future lymphoid neoplasm

Examining co-mutation patterns in those with a future LN diagnosis (Figure 4.4a-b) invites some initial speculation regarding the relationship between CH-PD and future LN. For many cases, the only CH-PD mutations detected occur in genes that are seldom implicated as drivers in the lymphoid cancer type diagnosed years later. The most notable example is *DNMT3A*, the most frequently mutated gene among both cases and controls (Figure 4.2a). Although *DNMT3A* does play a role in some lymphoid malignancies, particularly T-cell leukaemia/lymphoma (Couronne et al., 2012; Haney et al., 2016a; Haney et al., 2016b), it is not among the most recurrently mutated genes in these disorders (Brunetti et al., 2017; Sabarinathan et al., 2017). By contrast, the *BRAF* p.V600E, *POT1* p.K90E and *XPO1* p.E571 hotspot mutations preceding diagnoses of hairy cell leukaemia (HCL), small cell B-cell lymphoma (SLL) and CLL, respectively, are highly plausible drivers of the respective latent malignancies, but are rarely if ever associated with CH in the general population (Landau et al., 2015; Pinzaru et al., 2016; Tiacci et al., 2011).

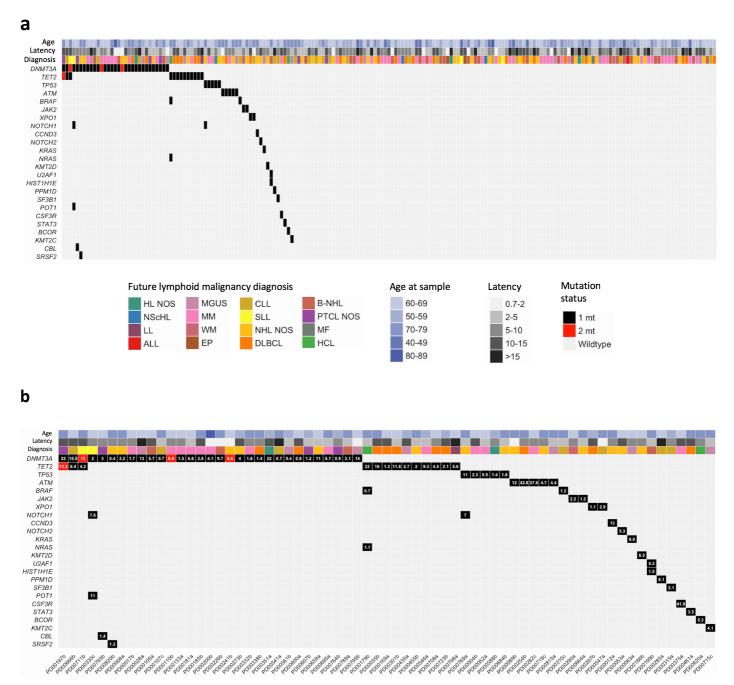

In order to further investigate the relationship between CH-PD detected years before LN diagnosis and the future malignancy, serial peripheral blood DNA samples were sequenced from 104 individuals, including 69 pre-LN cases and 35 controls. The mean interval between earliest and latest sample was 7.3 years. No diagnostic specimens were available; however, for 16 of the pre-LN cases, at least one peripheral blood sample taken less than 6 months before diagnosis (n = 5 individuals) or after diagnosis (n = 11 individuals) was sequenced.

Of the 69 serially sampled pre-LN cases, 22 had at least one driver detected in an earlier time point sample. Out of the 26 distinct mutations identified, 25 persisted in the later sample and 1 became undetectable. The only non-persistent clone harboured a *KRAS* p.G13D mutation present at 1% VAF in PD00003 at age 62.4 and no longer detectable in a sample taken 8.5 years later. Among the 35 controls with serial samples, 7 had mutations detected in their earlier samples. Of the 10 distinct variants, 5 persisted and 5 were no longer detected in the subsequent sample. The latter group comprised low VAF mutations in *DNMT3A* (n=4) and *KRAS* (n=1). Consistent with the patterns seen in pre-AML cases and controls, examining the VAF trajectories of the persistent mutations over time demonstrated variable behaviour, including for clones with mutations in the same gene (Figure 4.5a,b). However, the numbers

of cases and controls with mutations were insufficient to infer any significant overall difference in clonal growth rates between pre-LN cases and controls.

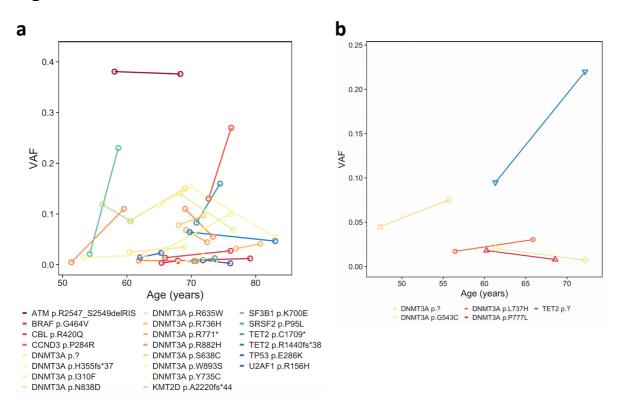

Examining the sequence of mutation acquisition and VAF trajectories among the pre-LN cases revealed several notable findings (Figure 4.6a-k). Among the 16 pre-LN cases with peri- or post-diagnosis samples available, 7 harboured antecedent CH-PD. All 7 individuals harboured at least one driver in DNMT3A (Figure 4.6a-g), all of which persisted across serial samples. In 4/7 cases, the size of the DNMT3A clone(s) diminished over time (Figure 4.6a,d,f,g), and in 2 of these cases this decline coincided with late acquisition of at least one driver mutation in a canonical lymphoid cancer gene, specifically CCND3 and CREBBP in an NHL and SF3B1 in a CLL case (Figure 4.6d,g)(Chapuy et al., 2018; Lunning and Green, 2015; Mullighan, 2014; Okosun et al., 2014; Sabarinathan et al., 2017). The same phenomenon is observed in two other cases, with the appearance of a relatively LN-specific driver mutation (e.g., in NOTCH1, POT1 and HIST1H1E)(Sabarinathan et al., 2017; Swerdlow et al., 2016) years before diagnosis also coinciding with stable or falling VAF of mutations in the canonical CH/myeloid neoplasm drivers DNMT3A and U2AF1, respectively (Figure 4.6i,j). These observations strongly suggest the presence of distinct, potentially competing clones and supports the hypothesis that a significant proportion of the CH-PD in the pre-LN cases is not phylogenetically related to the future malignancy, despite large clone sizes in most instances. Four serially-sampled pre-LN cases harboured drivers in genes more frequently mutated in LN than in CH-PD, namely CCND3, ATM, BRAF and TP53 (Figure 4.4a), and in each of these cases VAF increased over time. Hence, despite limited data, this time series experiment suggests that CH-PD in pre-LN cases represents a combination of pre-malignant clones and 'bystander' clones, analogous to the situation observed in pre-AML.

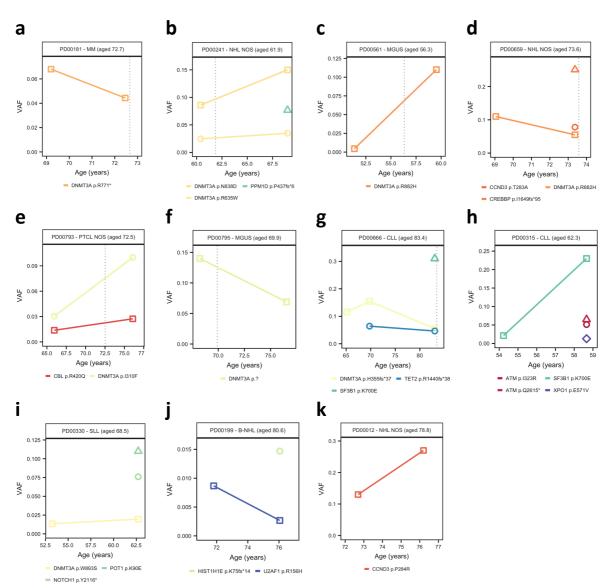

**Figure 4.4 | Mutation co-occurrence in pre-LN cases according to diagnosis, latency and age at sampling. a**, Co-mutation plot for all 189 pre-LN cases. Top three rows indicate age at sampling, latency and sample and future LN diagnosis. Tiles are coloured according to mutation status for each given gene and number of drivers identified: pale grey, wild type; black, one driver mutation; red, two driver mutations. **b**, Co-mutation plot including only cases with CH-PD. The mutation VAF percentage is indicated in white text within each tile. Where two mutations were identified in a given gene and sample (red tiles), the highest VAF is shown. MM, multiple myeloma; NHL NOS, non-Hodgkin lymphoma not otherwise specified; MGUS, monoclonal gammopathy of undetermined significance; DLBCL, diffuse large B-cell lymphoma; B-NHL, B-cell non-Hodgkin lymphoma; CLL, chronic lymphocytic leukemia; HCL, hairy-cell leukemia; PTCL NOS, peripheral T-cell lymphoma NOS; WM, Waldenstrom macroglobulinaemia; SLL, small cell B-cell lymphoma; HL, Hodgkin lymphoma; LL, lymphoblastic lymphoma; NSCHL, nodular sclerosis Hodgkin lymphoma; EP, extramedullary plasmacytoma; MF, mycosis fungoides; ALL, acute lymphoblastic leukemia.

#### 2.6 Clinical factors associated with future development of a lymphoid malignancy

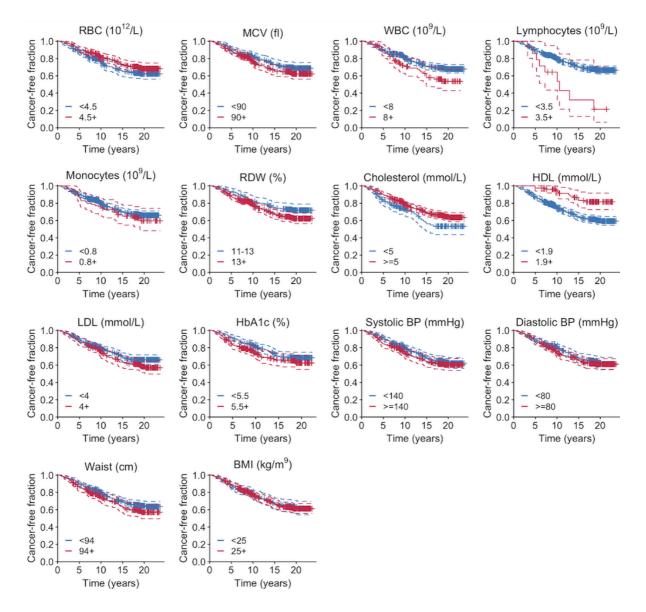

Full blood count parameters, lipid profile, C-reactive protein, blood pressure and anthropomorphic measurements were available for most of the pre-LN cases and controls (Figure 4.7). The case:control ratio for this analysis was 1:2 due to inclusion of 189 age-and sex-matched controls from the validation cohort described in Chapter 3. Consistent with the observations in the pre-AML cases and controls and previous studies of CH-PD (Jaiswal et al., 2014; McKerrell and Vassiliou, 2015), blood counts did not differ significantly between premalignant cases and controls or between individuals with and without CH-PD (Figure 4.7). Assessing all clinical parameters available for the majority of pre-LN cases and controls revealed significantly lower levels of high-density lipoprotein (HDL) in pre-LN cases (P=0.048, two-sided Wilcoxon rank-sum test with BH multiple testing correction). No other trends in clinical variables remained significant after multiple testing correction. There were no significant differences in clinical parameters when only cases and controls with CH-PD were compared to each other or when all individuals (cases and controls) with CH-PD were compared to individuals with no detectable mutations. Kaplan-Meier analysis of the impact of clinical variables on LN-free survival showed trends towards shorter time to cancer progression with higher RDW, though this correlation did not reach significance (Figure 4.8).

Figure 4.7

**Figure 4.7 | Full blood count and metabolic parameters in pre-LN cases and controls.** Box plots of full blood count parameters (**a-h**), biochemistry measurements (**i-n**), body mass index (**o**), waist circumference (**p**), and blood pressure (**q-r**) available for a subset of cases and pre-LN controls. Boxplot centres, hinges and whiskers represent the median, first and third quartiles and 1.5× interquartile range, respectively. RBC, red blood cell; MCV, mean corpuscular volume; WBC, white blood cell; RDW, red cell distribution width; HDL, high density lipoprotein; LDL, low density lipoprotein; HbA1c, haemoglobin A1c; CRP, C-reactive protein; BMI, body mass index; BP, blood pressure. \* *P*=0.048, two-sided Wilcoxon rank-sum test with BH multiple testing correction

#### 2.7 Predicting progression to lymphoid malignancy

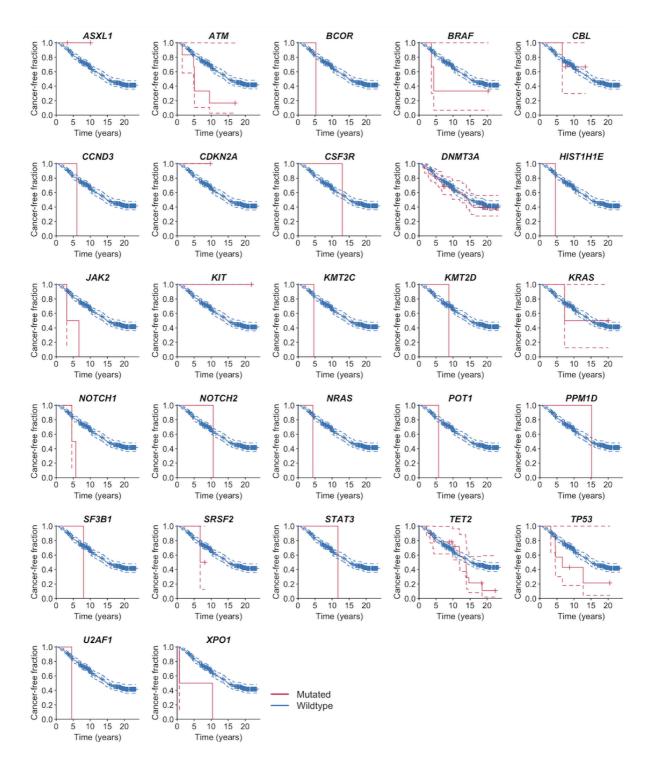

On the basis of these findings, an approach similar to that described in Chapter 3 was developed to quantify the relative contributions of driver mutations, clone sizes and clinical factors to the risk of progressing to a lymphoid malignancy. In keeping with results from Chapter 3, Kaplan-Meier analysis of the impact of the number of drivers and mutation VAF demonstrated consistent correlation between mutation burden and progression-free survival, though these trends did not reach significance (Figure 4.9a). This correlation held even when the additional set of controls was incorporated and analysis was restricted to genes included in the myeloid panel used in Chapter 3 (Figure 4.9b). Although the relative infrequency of CH among pre-LN cases limited the power of KM analysis, a trend towards shorter LN-free survival was observed with larger *DNMT3A* clones (Figure 4.9c) or the presence of mutations in any of the LN-associated genes *XPO1, POT1, CCND3, HIST1H1E, NOTCH1* or *NOTCH2* (Figure 4.9d). KM curves for individual genes are shown in Figure 4.10.

#### Figure 4.9

**Figure 4.9 | Impact of mutation burden on lymphoid neoplasm-free survival. a,b** Kaplan– Meier (KM) curves of LN-free survival, defined as the time between sample collection and LN diagnosis, death or last follow-up. Survival curves are stratified according to number of driver mutations per individual and largest clone detected. Panel **(a)** includes all genes sequenced across the 189 pre-LN cases and 189 age- and sex-matched controls. The same trends, albeit not reaching significance, persist when only mutations in genes sequenced by the myeloid panel are included in the analysis (189 pre-LN cases and 378 controls) **(b)**. **c,** KM curves of LN-free survival stratified by *DNMT3A* mutation status and VAF of *DNMT3A* mutations. **d,** KM curve of LN-free survival stratified according to mutation status in any of six infrequently mutated lymphoid neoplasm-associated driver genes. VAF, variant allele fraction.

#### Figure 4.10

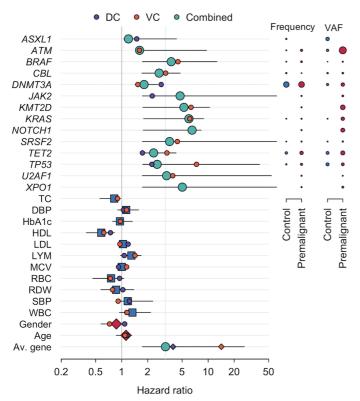

**Figure 4.10 | Gene-level impact on LN-free survival.** Kaplan–Meier (KM) curves of LN-free survival, defined as the time between sample collection and AML diagnosis, death or last follow-up. Survival curves are stratified according to mutation status. *n* = 378 unique individuals (189 pre-LN cases and 189 controls). LN, lymphoid neoplasm; VAF, variant allele fraction. Dashed lines indicate 95% confidence intervals.

However, the high proportion of infrequently mutated genes dominating the genetic landscape of CH-PD among pre-LN cases and lower prevalence of CH-PD among pre-LN relative to pre-AML hindered robust identification of gene-level risk factors for malignant progression. Regularised logistic and Cox proportional hazards regression approaches were applied as described in Chapter 3 (see Methods section 4). Excluding infrequently mutated genes from model training eliminated a significant proportion of CH-PD mutations from analysis and yielded fairly homogenous gene-level hazard ratios with wide confidence intervals for most genes (Figure 4.11). Notable exceptions were DNMT3A and TET2, which were the most recurrently mutated genes across both cohorts and were thus amenable to more accurate analysis of the mutation contribution to LN progression risk (Figure 4.11a). Quantitatively, driver mutations in DNMT3A and TET2 conferred a 1.5 to twofold increased 10-year risk of LN per 5% increase in clone size (Figure 4.11a and Appendix 15). Remarkably, these hazard ratios are virtually identical to the effect sizes observed for these genes in the AML prediction model (Figure 3.5). In order to achieve more accurate estimates of HRs for clinical variables and the subset of genes sequenced across both gene panels, the model was retrained using an additional set of 189 controls sequenced with the myeloid panel used in Chapter 3 for a case:control ratio of 1:2. The genes analysed were restricted to those overlapping between both panels and mutated at least twice in either discovery or validation cohort. Hazard ratios for overlapping variables were concordant, albeit with narrower confidence intervals (Figure 4.11b).

#### Figure 4.11

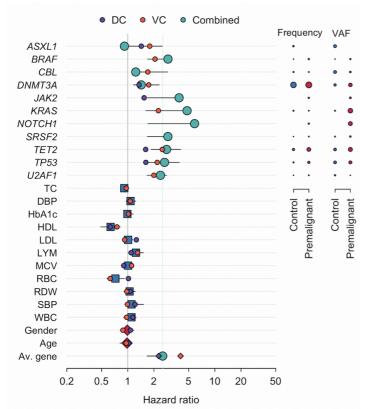

Figure 4.11 | Forest plots of hazard ratios for risk progression to lymphoid malignancy. a, Forest plot for Cox proportional hazards model using a 1:1 case control ratio and including all myeloid and lymphoid cancer genes. **b**, Model restricted to myeloid panel genes and incorporating an additional 189 age-and sex-matched controls for a 1:2 case:control ratio and hence more accurate estimates of risk associated with clinical factors and genes sequenced across both panels. Purple, orange and green circles indicate hazard ratios (HR) for the discovery (DC), validation (VC) and combined cohort, respectively. Horizontal lines denote 95% confidence intervals for the combined cohort. For each gene, the indicated HR applies to the 10-year risk of lymphoid blood cancer conferred by each 5% increase in mutation VAF. The green vertical line indicates the mean HR across all genes. Blue (controls) and red (pre-LN) circles to the right of the forest plot indicate the proportion of individuals with mutations in each gene and the average mutation VAF, which aids in the interpretation of hazard ratios. For example, ATM, a recurrent driver gene in several lymphoid malignancies, is almost exclusively mutated in pre-LN cases but at relatively high VAF, which translates into a modest HR for each 5% increase in clone size.

Overall, genetic and clinical parameters explained approximately 45% and 12% of the absolute variance in LN-free survival between individuals, respectively. Notably, clinical factors explained a comparable proportion of the variance. The coefficients for clinical variables were consistent between models trained on the discovery and validation cohorts (Figure 4.11a,b). Interestingly, lower HDL was associated with a modest but significant increase in risk of LN progression (Figure 4.11a,b). Consistent with this finding, lower total cholesterol was also associated with a smaller but still significantly increase in risk.

Unsurprisingly, models did not achieve anywhere near the predictive power observed for AML, with concordance and AUC both  $\leq$ 0.7 for models trained on either cohort (Table 4.2). Nevertheless, this analysis yielded robust estimates of the risk conferred by lower HDL levels and mutations in *DNMT3A* and *TET2*, findings with compelling biological implications that warrant further investigation.

 Table 4.2 Cox proportional hazard model performance

#### 3. Discussion

The main aim of this experiment was to characterise the prevalence and genetic landscape of CH-PD in individuals who go on to develop a lymphoid neoplasm. To this end, I have deep sequenced peripheral blood specimens from 189 pre-LN cases and 189 age- and sex-matched controls using a much broader gene panel than has been applied in previous similarly sensitive assays for CH. To investigate potential enrichment for LN-associated mutations in older age, this study was extended to include samples from a further 234 healthy older individuals. Serial samples, including peri- and post diagnosis blood samples, provided insight into clonal dynamics and the relationship between CH-PD and future malignancy. Clinical metadata, including full blood count parameters and lipid profile, were analysed for any association with CH-PD or future LN risk. Genetic and clinical variables were then incorporated into predictive models to seek any significant risk factors for LN progression and assess their collective power to identify individuals at high risk of future LN development.

## 3.1 CH-PD frequently precedes LN diagnosis and is characterised by a diverse mutational spectrum

This work demonstrates that CH-PD becomes more prevalent among individuals who develop a lymphoid malignancy years before diagnosis and is characterised by a more diverse genetic landscape than that observed in pre-AML cases or in the general population. The experiment described in Chapter 3 demonstrated that pre-AML exhibits a mutational spectrum that closely overlaps with that seen in the general population but is enriched for mutations in particular genes. By contrast, the pre-LN cohort harboured rare events in a number of genes highly associated with LN pathogenesis and rarely if ever reported in the current CH literature, including *ATM*, *CCND3*, *POT1*, *HIST1H1E*, *XPO1*, *NOTCH1* and *NOTCH2* (Arber et al., 2016; Kandoth et al., 2013; Martincorena et al., 2017; Sabarinathan et al., 2017; Swerdlow et al., 2016). Among these, *ATM* was the most recurrently mutated in pre-LN cases, ranking third after *DNMT3A* and *TET2*. The genetic heterogeneity observed in the pre-LN cohort is reminiscent of the genomic landscapes of the most common lymphoid blood cancers in adults, which tend to be characterised by a large number of infrequently mutated putative cancer genes (Landau and Wu, 2013; Reddy et al., 2017; Sabarinathan et al., 2017; Swerdlow et al., 2016).

#### 3.2 CH-PD as a biomarker for lymphoid blood cancer risk

Despite an overall more varied mutational spectrum in pre-LN CH-PD, the two top genes remained *DNMT3A* and *TET2*. Mutations in both of these genes, and in particular *TET2*, are implicated in both B- and T-cell lymphoid malignancies (Couronne et al., 2012; Dominguez et al., 2018; Haney et al., 2016a; Haney et al., 2016b; Mouly et al., 2018; Quivoron et al., 2011). TET2 deficiency in particular has been shown to increase HSC mutation rate and predispose to lymphoid and myeloid malignancies (Pan et al., 2017). However, the high

frequency of TET2/DNMT3A mutations in pre-LN CH-PD relative to lymphoid cancers, in conjunction with the results of the time series experiment, suggests that DNMT3A-mutated clones in particular often do not represent ancestors of the future cancer. Nevertheless, mutations in DNMT3A and TET2 confer a significantly increased risk for progression to LN, with hazard ratios comparable to those observed in the AML prediction model (Figure 3.5 and Figure 4.11). Although speculative, there are several possible explanations for this observation. As alluded to in Chapters 1 and 3, it is possible that clones that are not phylogenetically related to the future malignancy are surrogate markers of selective pressures that impart a strong growth advantage on pre-malignant HSCs. There is increasing precedent for this hypothesis in the haematopoietic system and other tissues. For example, as discussed in depth in Chapter 5, activating mutations in PPM1D, a negative regulator of TP53, confer a selective advantage on HSCs in the context of cytotoxic therapy (Gibson et al., 2017; Hsu et al., 2018; Takahashi et al., 2017). PPM1D-mutated CH-PD is a biomarker of therapy-related AML risk, despite that the PPM1D-mutations often persist at low VAF alongside the evolving AML (Gibson et al., 2017; Gillis et al., 2017). Remarkably, a similar scenario has recently been described in oesophageal epithelium, which is increasingly populated by *PPM1D*-mutated clonal expansions with age (Yokoyama et al., 2019). Exposure to alcohol and smoking, strong risk factors for oesophageal cancer, were associated with expansion of *PPM1D*-mutated epithelial clones, though *PPM1D* is not a recurrent driver in oesophageal malignancies (Yokoyama et al., 2019).

Current understanding of the selective pressures influencing somatic evolution in the haematopoietic system remains limited. However, age-related increases in endogenous genotoxic stress and reduced HSC self-renewal capacity may be important factors (Pang et al., 2017; Yahata et al., 2011). It is plausible that inter-individual variation in the pace and nature of age-related processes may influence the spectrum of mutations that confer selective advantage on HSCs. In this context it is noteworthy that *TP53* and *ATM*, both critical mediators of DNA damage response and cell cycle checkpoint control (Roos et al., 2016), constituted the third and fourth most frequently mutated genes in this pre-LN cohort. Whilst this result warrants confirmation in larger studies, it is conceivable that some individuals experience more severe/earlier DNA-damage associated HSC senescence and that this favours expansion of clones with mutations that repress DNA-damage-induced apoptosis and cell cycle arrest. By extension, such individuals would likely be at higher risk of stochastic

driver mutation acquisition and clonal evolution of any one of numerous pre-malignant clones. As mentioned in Chapter 3, Wong et al. recently reported a high prevalence of 'bystander' pre-leukaemic clones in AML patients at diagnosis, suggesting that their leukaemia arose from one of many candidate pre-malignant HSCs (Wong et al., 2015a).

### 3.3 RDW and lymphoid neoplasm risk

Notably, RDW was not significantly increased among pre-LN cases, in contrast to the scenario observed for pre-AML. As discussed in Chapter 3, higher RDW has previously been associated with CH in the general population (Jaiswal et al., 2014). However, we have shown that comparing pre-AML cases and controls with CH-PD revealed that RDW could help distinguish pre-AML (including cases without detectable CH-PD) from CH in individuals who did not develop a blood cancer during follow-up. The association between higher RDW and risk of developing AML was validated in a large electronic medical records dataset. It is possible that a weaker correlation does exists between pre-LN and RDW that this study was underpowered to detect, as hinted by the subtle trend discernible on KM analysis (Figure 4.8). However, this result nevertheless suggests that RDW is not a universally strong discriminator between indolent and pre-malignant CH-PD. This experiment may mask lymphoid cancer subtype-specific associations between RDW and warrants further investigation.

### 3.4 Lower high-density lipoprotein levels and lymphoid cancer risk

Among all clinical variables analysed, only HDL levels differed significantly between pre-LN cases and controls. The association between lower HDL and future LN was corroborated by Cox proportional hazards modelling, which identified a modestly increased risk of LN with lower HDL and total cholesterol (Figure 4.11a,b). Hypocholesterolaemia is a common finding in lymphoma and leukaemia patients, and has also been reported in association with some solid tumour types (Lim et al., 2007; Pirro et al., 2018). Lower HDL in particular has been previously identified as a preclinical feature of non-Hodgkin lymphoma discernible years before diagnosis (Lim et al., 2007). Low HDL at lymphoma diagnosis has also been correlated with poorer prognosis (Matsuo et al., 2017). The mechanisms underlying these observations are unclear with no compelling evidence of a causative link between low cholesterol and haematological malignancies (Pirro et al., 2018). However, numerous studies report that lymphoma cells and leukaemia blasts have higher HDL and/or LDL uptake receptor activity (Goncalves et al., 2005; Vitols et al., 1990; Vitols et al., 1985) and that cholesterol metabolism may represent a viable therapeutic target for several mature B-cell malignancies (McMahon et al., 2017). It is therefore possible that pre-malignant CH displays similar behaviour, leading to reductions in circulating levels of HDL even years prior to overt malignant transformation. This is a particularly intriguing hypothesis in view of the emerging causal role of CH-PD in atherosclerosis (Fuster et al., 2017; Jaiswal et al., 2017; Sano et al., 2018a). It is even conceivable that plaque-resident clonal haematopoietic cells may accelerate atheroma progression in part by increasing lipid accumulation at sites of inflamed endothelium.

# 3.5 Experiment limitations and future directions

This experiment has several important limitations. Firstly, the pre-LN cohort encompasses diverse diseases presenting over a long period during which histopathological classification schemes and diagnostic guidelines evolved considerably (Campo et al., 2011; Swerdlow et al., 2016). This limited the scope to investigate the natural history of or distinct genetic/clinical risk factors for individual cancer types. Furthermore, structural events, particularly translocations involving the immunoglobulin heavy chain (IGH) genes and numerical chromosomal aberrations, are frequent initiating events of lymphoid malignancies and their detection requires a much broader and more costly sequencing approach (Bolli et al., 2014; Landau et al., 2015). While the main aim of this experiment was to characterise the point mutation spectrum of CH-PD in pre-LN and investigate the predictive value of both putative ancestral and 'bystander' clones in assessing risk of progression, the power of predictive models would likely be increased by screening for subclonal large copy number changes and recurrent translocations.

Moreover, these results provide further evidence that malignant and cardiovascular adverse outcomes associated with CH might be linked. The association of lower HDL with LN progression risk, in conjunction with the clinical AML prediction model described in Chapter 3, hint that there may be unifying features of 'high risk' CH that could eventually help define a useful biomarker and/or therapeutic target. Hence this experiment reinforces the need for future studies of CH to correlate genetics with detailed clinical and phenotypic metadata and to try to move beyond investigating malignant and cardiometabolic disease associations in isolation.

# Chapter 5

# Clonal haematopoiesis after childhood cancer treatment

# 1. Introduction

The findings of the preceding chapters demonstrate that pre-malignant CH is associated with clinical and genetic features that can help distinguish individuals at highest risk of developing certain blood cancers, particularly *de novo* AML. These experiments studied individuals from the general population without a known history of cancer or haematological disorder. Further work will be necessary to adapt AML predictive models to patient groups prone to CH with distinct genetic features. As discussed in the general introduction, CH is particularly common in certain clinical contexts, notably aplastic anaemia and following cytotoxic treatment for an unrelated malignancy (Bowman et al., 2018). CH in adult cancer patients has recently become an active area of research due to the increasing numbers of cancer survivors at elevated risk of CH-associated pathology, including therapy-related myeloid neoplasms (t-MN) and earlier onset of common non-malignant conditions, particularly cardiovascular disease (Bowman et al., 2018; Carver et al., 2007; Morton et al., 2018). CH has emerged as a potentially promising biomarker for the risk of t-MN and other late effects of cancer treatment (Bolton et al., 2019; Coombs et al., 2017; Gibson et al., 2017; Gillis et al., 2017; Takahashi et al., 2017).

Childhood cancer survivors display an earlier onset of ageing-associated cardiometabolic conditions (Armstrong et al., 2016; Bhakta et al., 2017; Rowland and Bellizzi, 2014) and an elevated risk of t-MN and other secondary malignancies (Bhatia et al., 2007; Pui et al., 1991; Turcotte et al., 2018). Predicting and mitigating long-term complications of treatment is emerging as a dominant challenge in an era where a large proportion of children with cancer can be cured of their primary malignancy (Oeffinger et al., 2006). However, the

113

prevalence, genetic landscape and clinical significance of CH in this population is largely unknown.

The aims of the experiments described in this chapter were the following:

- 1) Evaluate whether CH is prevalent in childhood cancer survivors who have received intensive cytotoxic treatment and/or radiotherapy.
- 2) Investigate the natural history of a case of paediatric t-MN lacking an MLL rearrangement.

The following introduction provides an overview of existing literature on cytotoxic therapy related CH and the pathogenesis of t-MN.

# 1.1 Therapy-related myeloid neoplasms

### Epidemiology and risk factors

Therapy-related myeloid neoplasms comprise any AML or MDS arising after chemo and/or radiotherapy for a primary cancer, organ transplant or auto-immune condition (Arber et al., 2016). It constitutes one of the most challenging long-term complications of cancer treatment, with survival measured in months for most patients (Bhatia, 2013). Cytotoxic agents associated with the highest risk of t-MN are alkylating agents, topoisomerase II inhibitors and platinum-based drugs (Morton et al., 2018). The incidence and risk factors for t-MN have fluctuated as chemotherapy regimens for the commonest solid cancers have evolved (Bhatia, 2013; Morton et al., 2018). Over the past several decades, t-MN has accounted for a rising proportion of all newly diagnosed AML/MDS cases (Morton et al., 2018; Morton et al., 2014). Currently, t-MN constitutes around 10-20% of AML and MDS diagnoses, with an annual incidence of approximately 0.62/100,000 (De Roos et al., 2010; Hulegardh et al., 2015; Morton et al., 2018). A recent survey of all t-MN cases entered in the US SEER cancer registry between 2000 and 2014 found that nearly all solid tumour types were associated with t-MN, with the highest risk seen in patients treated for malignant bone tumours, followed by soft tissue sarcoma, testicular cancer, ovarian carcinoma and CNS malignancies (Morton et al. al., 2018). These findings represent a modest departure from previous epidemiological trends showing highest t-MN risk among breast cancer and lymphoma patients (Morton et al., 2010; Morton et al., 2018). Several solid tumour types were newly associated with t-MN risk, most likely reflecting recent introduction or increase in use of platinum agents to treatment protocols (Morton et al., 2018). Younger age at chemo/radiotherapy exposure correlated with higher t-MN risk, with high cumulative incidence of t-MN observed in children treated for solid tumours (5% to 11%) (Bhatia et al., 2007; Kushner et al., 1998; Le Deley et al., 2003; Morton et al., 2018).

Around 16-20% of t-MN patients harbour penetrant germline variants implicated in cancer susceptibility (Churpek et al., 2016; Felix et al., 1996; Schulz et al., 2012; Voso et al., 2015), compared with 9.5-12.6% of cancer patients overall and 1-2.7% of individuals without cancer (Pritchard et al., 2016; Schrader et al., 2016; Zhang et al., 2015). Cancer-predisposing germline mutations in t-MN patients are frequently reported in genes involved in mediating cellular responses to DNA damage, such as *BRCA1*, *BRCA2*, *BARD1* and *TP53* (Felix et al., 1996; Felix et al., 1998; Schulz et al., 2012). This observation may help explain the notorious chemoresistance of t-MNs (Bhatia, 2013; McNerney et al., 2017). Germline factors may constitute a particularly powerful risk factor in children at highest risk of t-MN. For example, children with soft tissue or bone malignancies have an 11% cumulative 5-year risk of t-MN (Bhatia et al., 2007). This patient group appears to have an exceptionally high burden of germline variants predisposing to cancer, identified in nearly 50% of individuals in the most recent survey (Ballinger et al., 2016).

#### Genomic landscape and classification

The somatic genomic features of t-MN are similar overall to those seen in non-therapy related myeloid neoplasms, but with dramatic enrichment for high-risk changes, notably rearrangements involving *KMT2A* (*MLL*) and *RUNX1*, *TP53* mutations and chromosome 5 and/or 7 losses (Bhatia, 2013; Smith et al., 2003). In adults, two subtypes of t-MN are delineated based on chemotherapy exposure, genomic features and clinical behaviour (McNerney et al., 2017). The alkylating agent-related class of t-MN constitutes around 70% of cases and is characterised by the high-risk cytogenetic changes del(5q) and -7/del(7q) and *TP53* mutations (in around 33%) (Heuser, 2016), a relatively long latency (5-7 years from

cytotoxic exposure) and a tendency to initially present as MDS progressing towards AML (McNerney et al., 2017). In addition to alkylating agents (e.g., cyclophosphamide, melphalan), this class of t-MN is associated with exposure to platinum-based agents (e.g., cisplatin, carboplatin) and purine analogues (e.g., azathioprine, fludarabine) (McNerney et al., 2017; Offman et al., 2004; Waterman et al., 2012). The second broad category of t-MN is associated with topoisomerase II inhibitor exposure (e.g., anthracyclines and etoposide)(McNerney et al., 2017). The topoisomerase II (TOP2) inhibitor class of t-MN typically presents as frank AML and has a shorter latency (median 2-3 years) (Heuser, 2016; Smith et al., 2003). This may in part be driven by translocations that are common in these t-MN involving *KMT2A* (*MLL*), *RUNX1* or *PML-RARA*, powerful oncogenic rearrangements that tend to require few cooperating events to trigger leukaemic transformation (Andersson et al., 2015; McNerney et al., 2017; Papaemmanuil et al., 2016; TCGA et al., 2013).

#### t-MN pathogenesis: chemotherapy-induced DNA damage or clonal selection?

Until recently, the conventional model of t-MN pathogenesis proposed that most cases were attributable to somatic driver events directly induced by cytotoxic agents (Bhatia, 2013). Many chemotherapy drugs associated with t-MN are mutagenic, and some are associated with particular patterns of genomic damage. For example, TOP2 inhibitors may increase the likelihood of reciprocal translocations by delaying ligation of double-strand breaks, thus prolonging the opportunity for recombination with DNA from another chromosome (Cowell and Austin, 2012). In keeping with this model, fusion oncogenes in t-MN arising post TOP2 inhibitor treatment tend to have breakpoints consistent with processing of 4-base staggered double-strand breaks from TOP2-mediated cleavage (Felix, 2001; Hasan et al., 2008; Mistry et al., 2005).

The alkylating agent class of t-MN is characterised by complex karyotypes, high numbers of copy number aberrations and *TP53* mutations in over a third of cases (Itzhar et al., 2011; Smith et al., 2003). Alkylating agents covalently modify DNA and promote DNA cross-linking double-strand breaks (Fu et al., 2012). It was thought that this genotoxicity induced structural changes and occasionally *TP53* mutations, with the latter contributing to genomic instability (Bhatia, 2013).

However, this model of t-MN pathogenesis was refuted by the work of Wong et al, who investigated the natural history of TP53-mutated t-MN (Wong et al., 2015b). Ultrasensitive duplex sequencing demonstrated that the TP53 driver mutation present (at clonal VAF) in the t-MN was usually detectable at very low levels (VAF 0.003-0.7%) in bone marrow samples taken prior to commencing cytotoxic treatment for the primary malignancy (Wong et al., 2015b). Furthermore, the point mutation burden and patterns did not differ between t-MN and *de novo* AML (Wong et al., 2015b). These findings suggested that cytotoxic treatment selected for pre-existing TP53-mutated HSCs, and that the cytogenetic complexity observed in the t-MNs reflected abrogation of the TP53-mediated DNA damage response and survival of cells that would otherwise have undergone apoptosis (Wong et al., 2015b). The clonal selection model was corroborated by a follow-up experiment in which TP53-mutated clones transplanted into mice only expanded if the animals were exposed to cytotoxic therapy (Wong et al., 2015b). Moreover, screening peripheral blood samples from a cohort of otherwise healthy elderly individuals (n=20) identified TP53 mutations at very low VAF (<0.1%) in 37% (Wong et al., 2015b). These mutations persisted over time with little or no clonal expansion, suggesting that they conferred minimal selective advantage in the absence of unusual levels of genotoxic stress (Wong et al., 2015b). A contemporaneous study by Ok et al. compared TP53 mutations in t-AML and de novo AML and found no evidence suggesting that TP53 drivers in the former were induced by distinct chemotherapy-related mutational processes: there were no differences in mutation distribution, sequence context or proportion of transitions versus transversions (Ok et al., 2015). The finding that t-MN TP53 drivers predate chemotherapy exposure has since been reproduced by other experiments (Schulz et al., 2015; Takahashi et al., 2017).

#### Clonal haematopoiesis as a biomarker for t-MN risk

An important role for clonal selection in t-MN pathogenesis was corroborated by recent studies investigating CH in cancer patients. CH is dramatically more prevalent in cancer survivors compared to individuals of the same age who have not been exposed to cytotoxic agents/radiotherapy and is enriched for mutations in *TP53* and its negative regulator *PPM1D* (Coombs et al., 2017; Gibson et al., 2017; Gillis et al., 2017; Takahashi et al., 2017). Numerous elegant studies in both mouse and human have demonstrated that cytotoxic agents and

radiotherapy promote expansion of HSCs harbouring *TP53* or *PPM1D* mutations (Bondar and Medzhitov, 2010; Hsu et al., 2018; Kahn et al., 2018; Wong et al., 2015b). In keeping with the clinical significance of CH in the general population, CH in cancer survivors is associated with higher risk of t-MN as well as with non-malignant adverse outcomes (Coombs et al., 2017; Gibson et al., 2017; Gillis et al., 2017; Takahashi et al., 2017).

#### Childhood t-MN

Although t-MN is a leading cause of death in paediatric cancer patients surviving their primary cancers, relatively little is known about its pathogenesis in children (Bhatia et al., 2007; Heuser, 2016; Kushner et al., 1998; Le Deley et al., 2003; Pui et al., 1991). The relative contributions of germline risk factors, chemotherapy-induced driver mutations and clonal selection are unclear. The genomic landscape of paediatric t-MNs has not been well characterised, complicating efforts to trace their clonal evolution. However, it is conceivable that the genetic basis overlaps with that of paediatric AML/MDS/MPN arising in the absence of cytotoxic therapy, possibly with enrichment for high-risk features as seen in adults. Compared to adult MDS, paediatric myeloid neoplasms are enriched for mutations in the RAS oncogenes as well as *RUNX1, SETBP1* and *ASXL1* (Locatelli and Strahm, 2018; Pastor et al., 2017). Furthermore, more than 30% of paediatric MDS patients have an inherited cancer predisposition or bone marrow failure syndrome compared to <5% of adults (Hasle, 2016). Deletions affecting chromosome 7 (-7/7q-) or chromosome 5 (-5/-5q) are present in around 25% and 1% of paediatric MDS cases, respectively (Hasle, 2016).

Allogeneic HSCT remains the only potential cure for paediatric t-MN (Locatelli and Strahm, 2018) and unlike their adult counterparts, most children with t-MN are HSCT candidates (Hasle, 2016; Locatelli and Strahm, 2018). Importantly, the only factor associated with improved overall survival in paediatric t-MN patients is shorter delay between t-MN diagnosis and transplant (Locatelli and Strahm, 2018; Maher et al., 2017). It is therefore conceivable that early detection and monitoring of patients at highest risk of progressing to t-MN could improve outcomes by minimising the interval between t-MN manifestations and allogeneic HSCT.

Current knowledge of paediatric t-MN natural history is limited to four case reports of children with MLL-rearranged (MLLr) t-MN after TOP2 inhibitor treatment (Blanco et al.,

2001; Megonigal et al., 2000; Ng et al., 2004; Robinson et al., 2008). As discussed above, there is some evidence that reciprocal fusions involving MLL may be directly induced by TOP2 inhibitors (McNerney et al., 2017). Consistent with this view, in each of these four cases, sensitive methods failed to detect the MLL fusion in blood or bone marrow samples taken before chemotherapy exposure (Blanco et al., 2001; Megonigal et al., 2000; Ng et al., 2004; Robinson et al., 2008). However, in three of the four case reports, the MLL fusion was detectable in blood and/or bone marrow over a year before t-MN presented clinically (17, 15.5, and 37 months latency in Blanco et al, Megonigal et al, and Robinson et al, respectively) (Blanco et al., 2001; Megonigal et al., 2000; Robinson et al., 2008). The shortest interval between MLLr detection and t-MN diagnosis (3 months) was reported by Ng et al in a child who developed t-MN only six months after diagnosis with hemophagocytic lymphohistiocytosis (Ng et al., 2004). These case reports offer some hope that even chemotherapy-induced fusion oncogenes generally associated with shorter latency to t-MN may be detectable early enough in disease evolution to enable monitoring and expedite definitive treatment. However, I could not identify any studies investigating the natural history of paediatric t-MN lacking an oncogenic fusion.

# 2. Results

### 2.1 Prevalence of CH-PD in childhood cancer survivors

To determine whether CH prevalence is elevated in children who have undergone intensive chemo/radiotherapy, we performed targeted deep sequencing of peripheral blood DNA from 84 paediatric cancer survivors to search for candidate driver mutations. The median age at cancer diagnosis was 4.5 years, and the commonest malignancies were acute lymphoblastic leukaemia (n=21), neuroblastoma (n=17) and non-Hodgkin lymphoma (n=10). Nineteen children had received a hematopoietic stem cell transplant (8 allogeneic and 11 autologous). The median interval between completion of cancer treatment and blood sampling was 6 years (range 2 - 25). Patient characteristics are summarised in Table 5.1 with details for each individual shown in Appendix 3.

Table 5.1	Cohort summary
-----------	----------------

Diagnosis	Number of individuals	Mean age at diagnosis (years)	Mean time since last chemo/radiotherapy (years)
Neuroblastoma	17	3.0	11.4
Rhabdomyosarcoma	7	5.5	6.7
Acute lymphoblastic leukaemia	21	4.2	6.8
Non-Hodgkin lymphoma	10	6.9	8.3
Germ cell tumour	4	10.0	5.1
Lymphoblastic lymphoma	3	6.1	7.8
Hodgkin lymphoma	6	14.6	5.6
Nephroblastoma	5	3.5	7.6
Hepatoblastoma	1	0.3	9.4
Ewing sarcoma	4	8.0	8.0
Non-rhabdomyosarcoma soft tissue sarcoma	2	7.7	6.0
Choriocarcinoma	1	12.8	3.5
Nasopharyngeal carcinoma	1	15.9	3.0
Langerhans cell histiocytosis	2	3.4	6.6

Multiplex PCR was used to amplify 32 selected regions of 14 genes frequently mutated in CH and t-MN, including hotspots in the RAS oncogenes *NRAS* and *KRAS* (recurrently mutated in paediatric MDS/MPN) and all exons of *TP53* and *PPM1D* (Table 5.2; Methods section 2.3)(Coombs et al., 2017; Gibson et al., 2017; Locatelli and Strahm, 2018).

Gene	Chromosome	Target codon/exon	
NRAS	1	p.G12D	
SF3B1	2	p.K666N; p.K700E	
DNMT3A	2	p.R882/p.R693C	
IDH1	2	p.R132H	
KIT	4	exon 17	
NPM1	5	p.L287fs*13	
JAK2	9	p.V617F	
KRAS	12	p.G12R	
IDH2	15	p.R140Q; p.R172K	
PPM1D	17	exons 1 - 6	
TP53	17	exons 1 - 12	
SRSF2	17	p.P95L	
ASXL1	20	exon 12	
U2AF1	21	p.S34F; p.Q157R	

Table 5.2 | Genomic regions sequenced by multiplex PCR

The median sequencing depth achieved across all regions of interest was 5,295X. No somatic mutations above the assay sensitivity threshold (VAF  $\geq$  0.008) were observed in any of the 84 long-term paediatric oncology follow-up patients nor in 3 children with no history of cancer (Methods section 3.2).

# 2.2 Tracing the evolution of a paediatric t-MN with driver mutations in *PTPN11* and *SETBP1* to emergence in early neuroblastoma treatment

As discussed in the introduction, studies of paediatric t-MN evolution have thus far been limited to case reports of children presenting with MLLr t-MN (Blanco et al., 2001; Megonigal et al., 2000; Ng et al., 2004; Robinson et al., 2008). The aim of this experiment was to retrace the emergence of a paediatric t-MN with genetic features akin to the alkylating agent class of adult t-MN described earlier.

#### Case Report

A 4-year old girl presented with high-risk, metastatic (stage 4) neuroblastoma with bone marrow involvement. Apart from focal neuroblastoma involvement, the initial bilateral staging trephines and aspirates showed normal trilineage haematopoiesis. Pre-treatment blood counts were normal. She was enrolled on the high-risk neuroblastoma SIOPEN trial protocol (HR-NBL-1.7/SIOPEN, NCT01704716) and underwent Rapid COJEC induction chemotherapy consisting of ten weeks of treatment with a total of five chemotherapy agents: carboplatin, etoposide, vincristine, cisplatin and cyclophosphamide at cumulative doses of 1.5g/m<sup>2</sup>, 1.4g/m<sup>2</sup>, 12g/m<sup>2</sup>, 320mg/m<sup>2</sup>, 4.2g/m<sup>2</sup>, respectively. Bilateral restaging bone marrow biopsies performed following completion of induction chemotherapy and count recovery (day 120 of treatment) remained positive for neuroblastoma infiltration. She therefore received additional induction chemotherapy to achieve metastatic remission, i.e., two cycles of TVD: Topotecan, Vincristine, Doxorubicin at cumulative doses of 15mg/m<sup>2</sup>, 4mg/m<sup>2</sup> and 90mg/m<sup>2</sup>, respectively. Platelet and neutrophil count recovery were unusually slow (3 months), though the child remained well with no infectious complications. Bone marrow examination following count recovery was normal, with cytomorphological examination negative for metastatic disease. Peripheral blood CD34+ stem cells (PBSC) were therefore harvested and she completed treatment, which included surgery, myeloablative therapy with busulfan and melphalan (BuMel), autologous PBSC rescue, irradiation of the site of primary disease (21 Gy), differentiation therapy (isotretinoin) and anti-GD2 immunotherapy. She remained well throughout, despite slow platelet and neutrophil count recovery after high-dose BuMel. Eight months after finishing treatment (32 months after diagnosis), she was incidentally noted on routine follow-up to have developed moderate peripheral cytopenia with Hb 102 g/dL, white cell count 2.3 x  $10^9$ /L, neutrophils 1.29 x  $10^9$ /L and platelets 91 x 10<sup>9</sup>/L. Bone marrow examination revealed <5% blasts and no evidence of neuroblastoma recurrence. G-banded bone marrow karyotyping revealed monosomy 7 in keeping with a developing t-MN. Two months later the patient suffered local neuroblastoma relapse and succumbed to disease progression soon thereafter.

#### Retracing molecular emergence of t-MN

We applied whole genome and deep targeted sequencing to identify driver events in the peripheral blood at the time of t-MN diagnosis (32 months after first chemotherapy). Sequences were analysed against the reference genome in order to call deleterious germline variants and to achieve maximum sensitivity for somatic changes (Methods section 3.5). In parallel, a matched analysis was performed using whole genome sequencing of parental blood samples. Median coverage of t-MN, maternal and paternal blood samples was 74X, 111X and 100X, respectively. Whole genome sequencing identified somatic complex changes in chromosome 7 (a major clone with 7q- and a subclone with complete monosomy 7) and canonical hotspot mutations in *PTPN11* and *SETBP1* (Figure 5.1 and Table 5.3). Both copy number and point mutation drivers variants were validated by deep targeted sequencing (Methods 3.3-3.6, Figure 5.1). Moreover, unmatched analysis identified a deleterious germline BARD1 p.E652fs\*69 mutation strongly associated with hereditary cancer predisposition (ClinVar accession numbers RCV000115621.5, RCV000200198.2) (De Brakeleer et al., 2010; Ramus et al., 2015; Schrader et al., 2016; Smith et al., 2016). Although this variant had not been detected by routine clinical genetics targeted screening for cancer predisposition during neuroblastoma work-up, it was also present at SNP VAF in the maternal blood sample.

In order to retrace the emergence of the t-MN clone, we performed ultradeep targeted sequencing (median coverage 25,000X) of bilateral bone marrow biopsies taken at the end of Rapid COJEC induction, 4.5 months into treatment and 29 months prior to t-MN presentation. Unfortunately, these were the earliest samples able to be sequenced, with no pre-treatment specimens available. The *PTPN11* p.G503E mutation was present in both left and right bone marrow biopsies at VAF of 0.12% and 0.09%, respectively. The *SETBP1* p.D868G mutation was detected in the left bone marrow biopsy at a lower VAF of 0.074%. These variants were detected by two algorithms, including shearwater, which accounts for the local error rate when calling subclonal mutations (Methods section 3.3) (Gerstung et al., 2012; Gerstung et al., 2014). Although sequencing of PBSC harvest is underway to further validate this finding, the depth of the sequencing and presence of the *PTPN11* in both marrow samples gives a reasonable degree of confidence in its validity. Furthermore, several reads supporting the bone marrow *PTPN11* mutation was subsequently identified by the clinical

diagnostic service using targeted sequencing on an orthogonal platform (Ion Torrent)(data not shown; personal communication from Dr Sam Behjati). The *SETBP1* mutation may be genuine in the left bone marrow and have escaped detection in the contralateral specimen due to rarity and stochastic molecule sampling, but nonetheless warrants additional validation. Copy number analysis of the targeted bone marrow sequencing revealed concordant changes consistent with recurrent copy number aberrations (CNAs) observed in neuroblastoma (Figure 5.1d,e) (Matthay et al., 2016), though lacked sensitivity to confidently call any chromosome 7 losses.

Sample ID	Month since	Clinical context	Sample type	Somatic driver events	
	NBL diagnosis			Mutation	VAF (%)
PD31013c 32			<i>PTPN11</i> G503E	51.0	
	32	t-MN diagnosis	Peripheral blood	SETBP1 D868G	50.0
	anaghteens		-7/7q-	-

Table 5.3 | Summary of samples and genetic abnormalities

# Figure 5.1

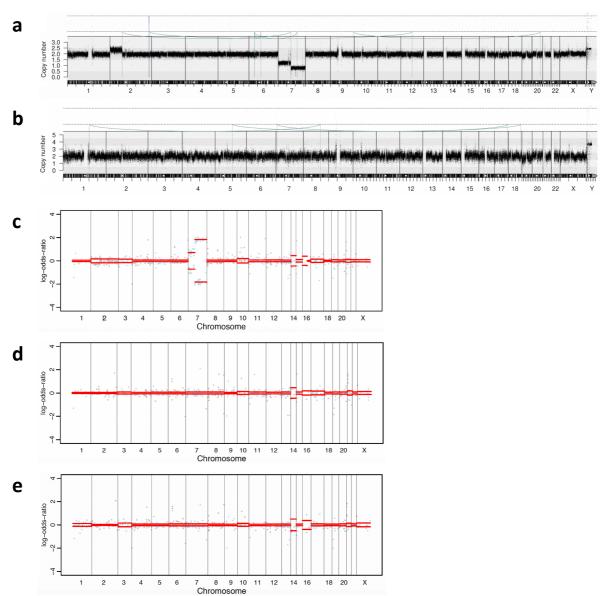

Figure 5.1 | Copy number profiles. a,b, Copy number changes and rearrangements detected from whole genome sequences of PD31013c (t-MN peripheral blood sample) (a) and PD31013d (right post-induction bone marrow biopsy) (b). The x axis shows chromosomal position and the y axis shows absolute copy number. Each dot in the plot represents the copy number of a particular genomic position (10 mega base bins). Coloured lines indicate breakpoints with rearrangements: brown, tandem duplication; blue, deletion; green and turquoise, inversion; grey, interchromosomal rearrangement. c-e, Copy number profiles derived from deep (>20,000x) targeted sequencing of t-MN (c) and bilateral bone marrow biopsies taken after induction chemotherapy, 15 months before t-MN emergence: PD31013d (right bone marrow) and PD31013e (left bone marrow) represented in panels (d) and (e), respectively. X-axis represents chromosome position. Y-axes represents allele-specific log-odds-ratio data with chromosomes alternating in blue and gray.

# 3. Discussion

The absence of any CH in the 84 heavily treated childhood cancer survivors screened stands in stark contrast to the situation recently observed in adults, where CH with candidate driver mutations is dramatically more common post chemo/radiotherapy than in the general population (Bowman et al., 2018; Gibson et al., 2017). Gibson et al. identified CH in over 25% of lymphoma survivors aged 30-39 and in over 40% of those aged 60-69 years (Gibson et al., 2017). Only 10 patients aged 20-29 were included in this study, none of whom had detectable CH, albeit using a less sensitive assay (detection threshold >2%)(Gibson et al., 2017). The most commonly mutated gene was PPM1D, which was captured in its entirety in our assay, followed by DNMT3A (most recurrent hotspot captured), TET2 (not captured) and TP53 (all exons captured) (Table 5.2)(Gibson et al., 2017). These findings have three plausible explanations. Firstly, somatic driver mutations may be extremely uncommon in the young even after exposure to chemotherapy, and hence the substrates for clonal selection are lacking. Secondly, it is possible that accrual of recognized 'driver' mutations is usually insufficient to trigger clonal expansion in the context of a very young haematopoietic niche. This hypothesis is supported by the fact that HSC mutations do begin accumulating early in life (Welch et al., 2012) and that the selective advantage of some CH drivers (most notably spliceosome gene mutations) appears to be age-dependent, implicating age-related changes in HSCs and/or their environment as key determinants of relative fitness (Link and Walter, 2016; McKerrell et al., 2015). This potential explanation is further supported by evidence that cancer-associated mutations are less able to drive clonal expansion in young compared to old stem cells (Zhu et al., 2016). Moreover, a recent study using ultra-sensitive sequencing of serially collected peripheral blood samples demonstrated that bona-fide driver mutations do not always lead to clonal expansion, even after several years (Young et al., 2016). Similar findings have been reported in other tissues, notably oesophagus and kidney, where oncogenic mutation acquisition has been timed to early childhood and adolescence, respectively (Mitchell et al., 2018; Yokoyama et al., 2019). The third potential explanation for our results is that the mutations under positive selection in paediatric cancer patients are so distinct from those observed in adult counterparts that this assay simply does not capture them. Our assay did include targets that are preferentially mutated in paediatric myeloid neoplasms – namely hotspots two RAS oncogenes and ASXL1 exon 12 – but lacked other

genes and hotspots that are likely to be enriched in paediatric t-MN or CH, notably *SETBP1*, *PTPN11* and *RUNX1* (Hasle, 2016; Tartaglia et al., 2003). In summary, these results should not necessarily be taken to reflect absence of potentially oncogenic HSC mutations in young cancer survivors. Rather, it is possible that even canonical CH driver mutations may not commonly drive clonal outgrowth in children and young adults despite exposure to cytotoxic drugs. More sensitive DNA sequencing methods may enable detection of very rare mutated cells in this patient group, which would lend support to this hypothesis. Equally, future sequencing studies assessing larger cohorts with a broader gene panel are warranted to explore the genetic landscape of paediatric CH. Ideally such work would be informed by a comprehensive understanding of the genomic features of paediatric t-MN, which is currently lacking.

The second experiment described in this chapter traced the emergence of t-MN during treatment for high-risk neuroblastoma. We applied deep targeted sequencing to track missense driver mutations in *PTPN11* to bone marrow samples taken at the end of induction chemotherapy. This case adds to the limited existing knowledge of paediatric t-MN evolution in several ways. Firstly, these findings contribute a fifth case to the literature suggesting that paediatric t-MN evolution typically becomes detectable very early in the treatment for the primary malignancy (Blanco et al., 2001; Megonigal et al., 2000; Ng et al., 2004; Robinson et al., 2008). In particular, this appears to be the first case reporting early molecular emergence of a non-MLLr case of paediatric t-MN. Although this patient was exposed to high doses of TOP2 inhibitors as well as platinum and alkylating agents, the clinical presentation and genomic features of this t-MN are reminiscent of the so-called alkylating agent class of adult t-MN with chromosome 7 loss, no fusion oncogene and an indolent clinical presentation with MDS rather than overt AML. In retrospect, the slow platelet and neutrophil count recovery following high-dose chemotherapy suggests early clinical manifestations of t-MN. This is in keeping with the tendency for paediatric MDS and MPN/MDS to present with neutropenia and/or thrombocytopaenia (Hasle, 2016; Kardos et al., 2003; Niemeyer and Baumann, 2011), whereas adult MDS most frequently manifests with isolated anaemia (Locatelli and Strahm, 2018; Raza and Galili, 2012). As mentioned earlier, the most frequent cooperating point mutation drivers in adult t-MN occur in TP53, whereas drivers in PTPN11 and SETBP1 are relatively rare (observed in 3-9% and 3% of adult t-MN cases, respectively) (McNerney et al.,

2017). However, mutations in these genes are enriched in paediatric MPN/MDS (Hasle, 2016; Locatelli and Strahm, 2018). Somatic *PTPN11* mutations in particular are a feature of high-risk paediatric MDS warranting prompt allogeneic HSCT (Locatelli and Strahm, 2018).

Moreover, the incidental discovery of a deleterious germline *BARD1* mutation by whole genome sequencing provides further evidence that the contribution of germline predisposition to t-MN (and childhood cancer in general) may be underestimated. *BARD1* is a tumour suppressor involved in regulating the DNA damage response and TP53-mediated apoptosis (Irminger-Finger and Jefford, 2006). Loss-of-function germline mutations have been implicated in susceptibility to a variety of cancers, including t-MN (Irminger-Finger and Jefford, 2006; Schulz et al., 2012).

All discussion of clinical ramifications of these findings remains highly speculative at this point. However, current evidence indicates that the only factor clearly associated with improved childhood t-MN survival is shorter interval between t-MN diagnosis and allogeneic HSCT (Locatelli and Strahm, 2018; Maher et al., 2017). Hence it is possible that earlier detection of early t-MN clones could help address a major cause of mortality in children with cancer (Bhatia et al., 2007; Heuser, 2016; Kushner et al., 1998; Le Deley et al., 2003; Pui et al., 1991). With specific regard to neuroblastoma patients, it is conceivable that early identification of patients who may later require an allogeneic HSCT for t-MN could alter the risk/benefit analysis vis a vis proceeding with myeloablative treatment and autologous PBSC rescue (Fish and Grupp, 2008; Yalcin et al., 2015).

Collectively these findings propose several follow-up experiments. Firstly, scant knowledge of the genomic landscape of paediatric t-MN warrants collaborative efforts to whole genome sequence a sizeable cohort exposed to a range of treatment protocols. This in turn will inform future studies of the prevalence and prognostic significance of CH in childhood cancer patients. In the first instance, targeted sequencing assays should include genes preferentially mutated in paediatric myeloid neoplasms, enough heterozygous SNPs to call subclonal chromosomal arm-level copy number changes and sufficient intron tiling to detect recurrent AML-associated rearrangements. These are tractable goals even with panels small enough for routine clinical use (McKerrell et al., 2016). In the first instance, a retrospective case-control study could help assess the utility of CH-PD as a biomarker of t-MN risk. However, given the high cumulative incidence of paediatric t-MN (Bhatia et al., 2007;

128

Heuser, 2016; Kushner et al., 1998; Le Deley et al., 2003; Pui et al., 1991), a prospective approach in the context of clinical trial also warrants consideration, particularly for neuroblastoma and sarcoma protocols associated with the highest risk (Bhatia, 2013; Bhatia et al., 2007; Kushner et al., 1998; Morton et al., 2018).

# Chapter 6

# Discussion

Collectively, this work has shed light on the landscape of clonal haematopoiesis in three distinct settings: in the years preceding a diagnosis of either AML (Chapter 3) or a lymphoid malignancy (Chapter 4) and following intensive cytotoxic therapy for a childhood cancer (Chapter 5). In this discussion I will highlight common themes emerging from the results of the preceding chapters and provide an overview of further questions and areas for methods development.

# 1. Overview of emerging concepts

# 1.1 Key points:

- CH in individuals who years later develop a haematological malignancy is characterised by a different genetic landscape compared to CH in the general population, not merely by a higher mutation burden.
- Predictive models incorporating genetic and demographic variables identify most individuals with CH at high risk of progression to AML. Mutations in *TP53* and *U2AF1* are associated with a higher risk of AML progression than somatic events in the most frequently mutated CH genes.
- Clones harbouring *DNMT3A* or *TET2* mutations confer similar risks of progressing to AML versus a lymphoid neoplasm.
- Readily available clinical information improves CH risk-stratification. Higher RDW helps discriminate indolent CH from pre-AML. Lower cholesterol is reaffirmed as a likely biomarker of both lymphoid and myeloid malignancy risk.

 This work adds to the preliminary evidence suggesting that evolution of childhood t-MN may frequently be detectable early in treatment for the primary malignancy. For childhood cancer patients, the relative rarity of CH, heavy burden of t-MN and survival advantage of prompt HSCT highlight this patient group as a top priority for further study of the clinical utility of CH screening.

# 1.2 The mutational spectrum of premalignant CH

The prevalence, number of driver mutations and clone sizes all tended, unsurprisingly (Genovese et al., 2014; Jaiswal et al., 2014), to be markedly higher among individuals who later developed a blood cancer. However, there were also significant differences in the genetic landscape of CH in these different contexts. Within the pre-AML cohort, the spectrum of CH drivers overlapped with that seen in the general population, but was enriched for spliceosome mutations in younger individuals. By contrast, the mutational landscape preceding lymphoid cancer diagnosis was remarkably diverse, with a long 'tail' of driver mutations in genes seldom if ever implicated in CH in the general population but highly associated with lymphoid neoplasms.

# 1.3 CH as a biomarker of blood cancer risk irrespective of phylogenetic relationship with future malignancy

Several findings reported here add to the growing evidence that CH is a risk factor for haematological malignancy even when not related to the future neoplastic clone. Models estimating future AML or LN risk demonstrated that the number, clone size and specific genes mutated all carried predictive value. Although the power to discern gene-level risk for the pre-LN cohort was limited by the large number of infrequently mutated genes, a key finding from the LN predictive models was that *DNMT3A* and *TET2* mutations were robustly predictive of future LN risk, and that hazard ratios were equivalent to those observed for AML progression. Given that *DNMT3A* and *TET2* are much less frequently implicated as drivers in lymphoid compared to myeloid cancers, this finding suggests that CH can be a biomarker of blood cancer risk independent of the relationship between the CH clone and future malignancy. This is in keeping with observations that CH is a biomarker for t-MN risk in adult cancer patients, despite that the antecedent CH and future t-MN are often phylogenetically unrelated (Gibson et al., 2017; Gillis et al., 2017; Takahashi et al., 2017). Equally, a recent

study suggests that *de novo* AML frequently arises from one out of many co-existing independent CH clones detectable pre-treatment (Wong et al., 2015a).

The time-course experiment data in both Chapters 3 and 4 provide further insight into the relationship between CH and future malignancy risk. Variable clonal growth trajectories were observed in premalignant cases and controls. Many clones regressed over time, including some harbouring high VAF canonical hotspot mutations, e.g., DNMT3A p.R882H. Hence the cell-intrinsic self-renewal advantage conferred by such mutations (Brunetti et al., 2017) does not necessarily induce inexorable clonal expansion over time, despite that they collectively confer higher leukaemia risk. Among the few pre-AML for whom diagnostic or peri-diagnostic specimens were available, most clones, though not all, expanded and appeared likely to contribute to the AML. The pre-LN serial sampling data offers even more compelling evidence that mutations unrelated to the future cancer are *bona fide* biomarkers of malignant transformation risk. Comparing pre-LN cases to controls revealed that DNMT3A mutations were present at significantly higher VAF in pre-LN cases. Nevertheless, even large (VAF>5%) DNMT3A-mutated clones often declined in size leading up to cancer diagnosis, frequently coinciding with the appearance of new, LN-associated drivers. Hence it is likely that most of the predictive power of DNMT3A mutations does not stem from their direct contribution to LN evolution.

Collectively, these experiments, in conjunction with the aforementioned t-MN studies, strongly suggests that CH unrelated to the future malignant clones is nevertheless a biomarker of malignant transformation risk. There are several non-mutually exclusive potential explanations for this observation. It is possible that the HSC mutation rate, and hence the likelihood of serial acquisition of drivers in any given clone, tends to be higher among individuals who develop a cancer, and the presence of multiple detectable clones is a surrogate marker of the higher mutation rate. However, the mutation burden and signatures in AML compared to normal HSCs of the same age argue against this as a universally active mechanism (Alexandrov et al., 2013; Welch et al., 2012). Alternatively, CH may be a surrogate marker of the presence/intensity of selection pressures that influence the fitness advantage conferred by particular driver mutations. Studies of CH in the context of aplastic anaemia (Yoshizato et al., 2015) and cytotoxic therapies (Gibson et al., 2017; Hsu et al., 2018; Kahn et al., 2018) provide strong evidence that extrinsic selective pressures can dramatically increase the prevalence of CH, shape the genetic landscape, and increase the malignant

transformation risk. By extension, it is conceivable that the same may be true for diverse subtler extrinsic selection pressures, e.g., arising from variable ageing processes, environmental exposures, or inter-individual genetic variation. For example, physiological ageing processes occur at different rates in different individuals (Andersen et al., 2012; Finkel et al., 2007; Lopez-Otin et al., 2013). It is conceivable that age-associated increases in endogenous genotoxic stress (Rossi et al., 2007) and declines in HSC self-renewal capacity (Flach et al., 2014; Geiger et al., 2013) occur earlier or more severely in some individuals. This in turn could confer selective advantage on many mutated HSCs, increasing the number of detectable clones in younger age groups and the probability of any one of the clones acquiring additional oncogenic hits. These questions warrant further investigation, as discussed below.

# 2. Further questions and methodological challenges

### 2.1 To what extent is mutation acquisition a rate-limiting step in CH evolution?

Understanding the relative importance of mutation acquisition and extrinsic selective pressures in CH pathogenesis is an important gap in knowledge, not least for informing any future intervention strategies. For certain genes, e.g., TP53, very sensitive sequencing assays have demonstrated that driver mutations are common in older individuals at extremely low VAF and tend to be stable over time in the absence of any environmental selective pressures which increase mutated HSC fitness advantage (Wong et al., 2015b). By contrast, the exponential increase in the prevalence of CH harbouring spliceosome gene mutations observed in individuals aged >70 years (McKerrell et al., 2015) is poorly understood. It is possible that this phenomenon reflects ageing-associated changes in the haematopoietic niche (McKerrell and Vassiliou, 2015). For instance, spliceosome mutations may generate neoantigens that elicit a stronger immune response in younger individuals (McKerrell and Vassiliou, 2015). However, this speculation has yet to be supported by experiments demonstrating low-level persistence of rare HSCs carrying spliceosome mutations in younger individuals. The sensitivity of error-corrected sequencing assays has been a major obstacle to this type of experiment (Kennedy et al., 2014; Schmitt et al., 2012). In particular, sensitivity is hindered by target pulldown efficiency and stochastic molecular sampling, issues which can

be partially circumvented by multiple target enrichment steps and using a limited number of cells as starting material (Schmitt et al., 2015). However, novel methods of increasing sensitive, accurate detection of specific mutations (Nachmanson et al., 2018; Newman et al., 2016) could be applied to the detection of canonical spliceosome gene hotspot driver variants in younger cohorts.

# 2.2 Haematopoiesis and ageing in health and disease

To what extent do the number, mutation rate, and clonal dynamics of haematopoietic stem and progenitor cells vary between individuals? These are pertinent questions for understanding the increased CH burden seen in individuals who later develop a haematological malignancy, as discussed above. Two recent studies have used somatic mutations to study clonal dynamics in native human haematopoiesis (Lee-Six et al., 2018; Osorio et al., 2018). Based on this work, it is likely that there are circa 50,000-200,000 HSCs contributing to haematopoiesis, dividing roughly every 2-20 months with around 14 mutations introduced per cell division (Lee-Six et al., 2018; Osorio et al., 2018). Applying similar approaches, potentially with superimposed phenotypic information, to many individuals across the age range and in disease/cancer-predisposition states will likely give valuable insights into haematopoietic ageing and CH pathogenesis.

### 2.3 Refining CH detection methods

The definition and terminology used to describe CH has evolved rapidly and sometimes included VAF cut-offs (Bejar, 2017). However, the latter have been decided based on technical limitations rather than mature understanding of what constitutes clinically significant CH (Bejar, 2017; Steensma et al., 2015). In future, cheaper sequencing should enable comprehensive assays to detect subclonal cancer-associated structural events in addition to point mutations. Novel sequencing methods for detecting rare somatic mutations, notably bottleneck sequencing (BotSeq), may enable broader screens for genes under positive selection in CH (Hoang et al., 2016). Briefly, BotSeq combines molecular barcoding with a subsequent dilution step, permitting highly accurate detection of rare mutations across the entire genome without the need to achieve prohibitively expensive sequencing depth. It is conceivable, though currently entirely speculative, that transcriptional or methylation-

based signal may also be amenable to identifying and characterising CH and may warrant exploration in tandem with future studies of genomically-defined CH.

# 2.4 Prospective longitudinal studies of CH and potential intervention strategies

An important next step will be to establish large prospective longitudinal studies enabling validation and refinement of combined genomic-clinical CH risk prediction models. Ideally such studies will examine multiple clinically relevant sequelae of CH and permit identification of high-risk groups that might benefit from intervention. The nature of potential interventions is speculative at present. An increasing arsenal of targeted therapies active against recurrent cancer-associated CH mutations, including those in splicing genes (Lee et al., 2016), JAK2 (Van den Neste et al., 2018; Vannucchi and Harrison, 2016) and IDH1/2 (Döhner et al., 2015), may warrant investigation in high-risk CH. Moreover, two recent studies suggest that a much less costly option, ascorbic acid (vitamin C), helps restore TET2 function in HSCs and stall leukaemia progression (Agathocleous et al., 2017; Cimmino et al., 2017). Lastly, this work further corroborates a long-recognised connection between hypocholesterolaemia and haematological malignancies. Lower HDL and LDL were both risk factors for AML in the clinical risk prediction model discussed in Chapter 3. Lower HDL was associated with a higher risk of developing a lymphoid neoplasm (Chapter 4). The latter result corroborates previous work identifying low HDL as a biomarker of future lymphoma risk years prior to diagnosis (Matsuo et al., 2017). Hypocholesterolaemia is common among blood and solid cancer patients and is inversely correlated with cancer cell LDL-/HLD-receptor activity (Ho et al., 1978; Vitols et al., 1985; Vitols et al., 1984; Vitols et al., 1992). A mendelian randomisation study by Benn et al. found that the correlation between low LDL and cancer was absent in individuals with genetic predisposition to hypocholesterolaemia, suggesting a causal link (Benn et al., 2011), though this remains contentious (Pirro et al., 2018). Pharmacologic agents targeting HDL uptake receptors and other targets involved in cholesterol metabolism have shown early evidence of therapeutic potential in several haematological malignancies (Crusz and Balkwill, 2015; McMahon et al., 2017; Pandyra et al., 2014). Interestingly, statin treatment is associated with a significant relative risk reduction for several solid tumours as well as cardiovascular disease (Demierre et al., 2005; Poynter et al., 2005). The molecular mechanisms underpinning these observations are poorly

understood and may involve pleiotropic effects on multiple processes relevant to oncogenesis, including angiogenesis and inflammation (Crusz and Balkwill, 2015; Demierre et al., 2005; Hanahan and Weinberg, 2011). Collectively, these observations suggest that existing agents targeting cholesterol metabolism (Pandyra et al., 2014) warrant investigation as potential strategies for mitigating cardiovascular disease and cancer risks associated with CH.

In summary, the degree to which clones at high risk of malignant transformation - in blood and other tissues - can be reliably distinguished from their indolent counterparts is an important biological question with compelling clinical ramifications. This dissertation has explored the ability of genetic and clinical factors to identify individuals at high risk of AML and other haematological malignancies. Understanding the selective pressures and cellintrinsic mechanisms governing clonal fate is the next important step in developing strategies to predict and prevent progression to overt malignancy.

# 2 AML incidence data

Use known AML incidence to correct bias using weighted controls. The expected incidence of AML was calculated from the UK office of national statistics, available at http://www.cancerresearchuk.org/health-professional/cancer-statistics/statistics-by-cancer-type/leukaemia-aml/incidence (http://www.cancerresearchuk.org/health-professional/cancer-statistics/statistics-by-cancer-type/leukaemia-aml/incidence). Spline function to interpolate Male denoted by 1 and female by 0

#### Appendix 11: AML prediction model based on electronic health record data

#### AML case ascertainment from Clalit database

Cases included with diagnosis 205.0*	1696
Exclusion criteria	Number of retained cases
Prior diagnosis among the following:	
•ESSENTIAL THROMBOCYTHEMIA	
<ul> <li>HIGH/LOW GRADE MYELODYSPLASTIC SYNDROME LESIONS</li> </ul>	
<ul> <li>MYELODYSPLASTIC SYNDROME WITH 5Q DELETION</li> </ul>	
<ul> <li>MYELODYSPLASTIC SYNDROME, UNSPECIDIED</li> </ul>	1431
POLYCYTHEMIA VERA	1451
MYELOFIBROSIS	
<ul> <li>OPERATIONS ON BONE MARROW AND SPLEEN</li> </ul>	
<ul> <li>CHRONIC MYELOMONOCYTIC LEUKEMIA</li> </ul>	
•CHRONIC MYELOID LEUKEMIA	
Received medications suggesting alternative diagnosis:	
•IMATINIB	
•DASATINIB	
METHOTREXATE	
TRETINOIN	
•DASATINIB	1210
ANAGRELIDE	
<ul> <li>HYDROXYCARBAMIDE</li> </ul>	
<ul> <li>ASPARAGINASE</li> </ul>	
<ul> <li>PEGASPARGASE</li> </ul>	
ARSENIC TRIOXIDE	
No record of hospitalisation near time of diagnosis	1042
Age < 18	960
Received 6-mercaptopurine post diagnosis	
Multiple doses	929
<ul> <li>Combined with ALL diagnosis</li> </ul>	
Filter on onset year >=2003	875
	875
Total number of AML cases retained	8/5

#### Laboratory test result variables

Parameters included in clinical model	
Haematocrit (HCT)	SPECIFIC GRAVITY
Mean corpuscular volume (MCV)	CK-CREAT.KINASE(CPK)
Red blood cell count (RBC)	PT-INR
Haemoglobin (HGB)	MICRO%/HYPO%
mean corpuscular hemoglobin (MCH)	VITAMIN B12
mean corpuscular hemoglobin concentration (MCHC)	IRON
White blood cell count (WBC)	PT%
Platelet count (PLT)	Prothrombine time (PT- SEC)
Lymphocyte percentage (LYM%)	Chloride (Cl)
Neutrophil percentage (NEUT%)	LIPEMIC
Eosinophil percentage (EOS %)	ICTERIC
Monocyte percentage (MON%)	HEMOLYTIC
Basophil percentage (BASO %)	HEMOGLOBIN A1C CALCULATED
Absolute lymphocyte count (LYMP.abs)	СН
Absolute neutrophil count (NEUT.abs)	GLOBULIN
Absolute eosinophil count (EOS.abs)	FERRITIN
Absolute monocyte count (MONO.abs)	T4- FREE
BASOPHILES (abs)	APTT-sec
Mean platelet volume (MPV)	FOLIC ACID
Red cell distribution width (RDW)	PDW
CREATININE- BLOOD	Myeloperoxidase index (MPXI)
GLUCOSE- BLOOD	TRANSFERRIN
UREA- BLOOD	PCT
SODIUM	CHOLESTEROL HDL RATIO
POTASSIUM	BILIRUBIN INDIRECT
GLUTAMIC OXALOACETIC TRANSAMINASE	HCT/HGB RATIO
GLUTAMIC PYRUVIC TRANSAMINASE	CREATININE URINE SAMPLE
MICR %	SEDIMENTATION RATE
HYPO %	ERYTHROCYTES
MACRO%	LEUCOCYTES
PHOSPHATASE- ALKALINE	C-REACTIVE PROTEIN (CRP)
CHOLESTEROL	RDW-CV
TRIGLYCERIDES	M.ALBUM/CREAT RATIO
LUC%	AMYLASE- BLOOD
LUC	MICROALBU U SAMP
CHOLESTEROL-HDL	PROTEIN
CALCIUM- BLOOD	MAGNESIUM- BLOOD
HYPER%	Hemoglobin distribution width
URIC ACID- BLOOD	FIBRINOGEN
CHOLESTEROL-LDL	SODIUM- BLOOD
BILIRUBIN TOTAL	VITAMIN D3-25-0H-RIA
ALBUMIN	POTASSIUM- BLOOD
PROTEIN-TOTAL-BLOOD	RDW-SD
PHOSPHORUS- BLOOD	Prostate specific antigen (PSA)
TSH (THYROID STIMULATING HORMONE)	T3- FREE
LACTIC DEHYDROGENASE (LDH) -BLOOD	Activated partial thromboplastin time
GAMMA-GLUTAMYL TRANSPEPTIDASE	NORMOBLAST.%
BILIRUBIN- DIRECT	ESTRADIOL (E-2)
NON-HDL CHOLESTEROL	Absolute normoblast count
PH-u	Leutinising hormone (LH)
riru	Leadinising normone (LH)

#### Diagnostic code variables

Diagnoses	included in clinical model
ACUTE BRC	NCHITIS
ACUTE NAS	OPHARYNGITIS (COMMON COLD)
ANEMIA OT	THER/UNSPECIFIED
ANEMIA, U	NSPECIFIED
BACK SYMP	PTOMS/COMPLAINTS
CELLULITIS	AND ABSCESS OF UNSPECIFIED SITES
CHRONIC R	RENAL FAILURE
COLITIS, EN	TERITIS, GASTROENTERITIS PRESUMED INFECTIOUS ORIGIN
CONGESTIV	/E HEART FAILURE
CONTACT D	DERMATITIS AND OTHER ECZEMA, UNSPECIFIED CAUSE
DEBILITY, L	JNSPECIFIED
DERMATOR	PHYTOSIS OF FOOT
DISEASES A	ND CONDITIONS OF THE TEETH AND SUPPORT.STRUCTURES
DISTURBAN	ICE OF SKIN SENSATION
ESSENTIAL	HYPERTENSION
FEVER	
INFERTILIT	Y, FEMALE
IRON DEFIC	CIENCY ANEMIA, UNSPECIFIED
MIXED DIS	ORDERS OF CONDUCT EMOTIONS
OSTEOARTH	HROSIS AND ALLIED DISORDERS
PAIN IN LIN	ИВ
PNEUMON	IA, ORGANISM UNSPECIFIED
VARICOSE	VEINS OF LOWER EXTREMITIES

The incidence of acute myeloid leukaemia (AML) increases with age and mortality exceeds 90% when diagnosed after age 65. Most cases arise without any detectable early symptoms and patients usually present with the acute complications of bone marrow failure<sup>1</sup>. The onset of such de novo AML cases is typically preceded by the accumulation of somatic mutations in preleukaemic haematopoietic stem and progenitor cells (HSPCs) that undergo clonal expansion<sup>2,3</sup>. However, recurrent AML mutations also accumulate in HSPCs during ageing of healthy individuals who do not develop AML, a phenomenon referred to as age-related clonal haematopoiesis (ÅRCH)<sup>4-8</sup>. Here we use deep sequencing to analyse genes that are recurrently mutated in AML to distinguish between individuals who have a high risk of developing AML and those with benign ARCH. We analysed peripheral blood cells from 95 individuals that were obtained on average 6.3 years before AML diagnosis (pre-AML group), together with 414 unselected age- and gendermatched individuals (control group). Pre-AML cases were distinct from controls and had more mutations per sample, higher variant allele frequencies, indicating greater clonal expansion, and showed enrichment of mutations in specific genes. Genetic parameters were used to derive a model that accurately predicted AML-free survival; this model was validated in an independent cohort of 29 pre-AML cases and 262 controls. Because AML is rare, we also developed an AML predictive model using a large electronic health record database that identified individuals at greater risk. Collectively our findings provide proof-of-concept that it is possible to discriminate ARCH from pre-AML many years before malignant transformation. This could in future enable earlier detection and monitoring, and may help to inform intervention.

To examine the occurrence of somatic mutations before the development of AML, we carried out deep error-corrected targeted sequencing of AML-associated genes in a discovery cohort of 95 pre-AML cases and 414 age- and gender-matched controls (Supplementary Table 1). A validation cohort comprising 29 pre-AML cases and 262 controls (Supplementary Table 1) was analysed using deep sequencing with an overlapping gene panel. Taking both cohorts together, ARCH, defined on the basis of putative driver mutations (ARCH-PD), was found in 73.4% of the pre-AML cases at a median of 7.6 years before diagnosis. By contrast, ARCH-PD was observed in 36.7% of controls ( $P < 2.2 \times 10^{-16}$ , two-sided Fisher's exact test; Fig. 1a), consistent with data from a study of more than 2,000 unselected individuals assayed using a similarly sensitive method<sup>9,10</sup>. Additionally, 39% of pre-AML cases above the age of 50 had a driver mutation with a variant allele frequency (VAF) of more than 10%, compared to only 4% of controls,

#### LETTER RESEARCH

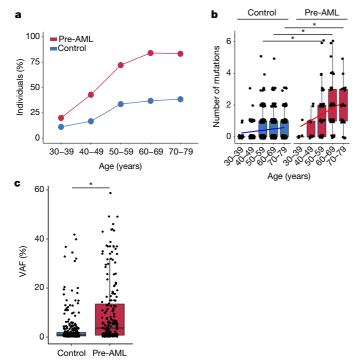

Fig. 1 | Prevalence of ARCH, number of mutations and clone size in individuals who developed AML. a, Prevalence of ARCH-PD among pre-AML cases (red) and controls (blue). b, The number of ARCH-PD mutations detected in cases and controls according to age. Box plot centres, hinges and whiskers represent the median, first and third quartiles and 1.5× interquartile range, respectively. Individual values are indicated as dots. c, VAF of ARCH-PD mutations. \*P < 0.0005, two-sided Wilcoxon rank-sum test with Bonferroni multiple testing correction. All panels show data for n = 800 biologically independent samples.

a prevalence that is in line with the largest studies of ARCH in the general population<sup>4</sup> ( $P < 2.2 \times 10^{-16}$ , two-sided Fisher's exact test; Extended Data Fig. 1).

The median number of ARCH-PD mutations per individual increased with age and was significantly higher in the pre-AML group relative to controls (Fig. 1b and Supplementary Table 2). Furthermore, examination of ARCH-PD VAF distribution revealed significantly larger clones among the pre-AML cases ( $P = 1.2 \times 10^{-13}$ , twosided Wilcoxon rank-sum test; Fig. 1c). To gain insight into clonal growth dynamics, we examined serially collected samples that were available for a subset of the validation cohort. We did not find significant differences in clonal expansion rates between pre-AML cases and controls (Extended Data Fig. 2a, b), although this may in part reflect the shorter follow-up of pre-AML cases, small sample size and large variance in growth rates (Extended Data Fig. 2c). The observed differences between pre-AML cases and controls may arise through cell-intrinsic or -extrinsic factors. Although these variables have not been adequately studied in ARCH, a number of observations in different contexts, such as aplasia, advanced age and after chemotherapy, have shown that increased clonal fitness is associated with distinct mutations depending on context<sup>10–12</sup>. Notably, mutations in splicing factor genes were significantly enriched among the pre-AML cases relative to the controls (odds ratio, 17.5; 95% confidence interval, 8.1–40.4;  $P = 5.2 \times 10^{-16}$ two-sided Fisher's exact test) and were present in significantly younger individuals (median age 60.3 compared to 77.3 years,  $P = 1.7 \times 10^{-4}$ , two-sided Wilcoxon rank-sum test; Fig. 2a). Previous work suggests that spliceosome mutations appear to confer a competitive advantage in the context of ageing<sup>10</sup>. Therefore, it is possible that the significantly higher prevalence of such clones in younger pre-AML cases may reflect extrinsic selection pressures rather than earlier mutation acquisition.

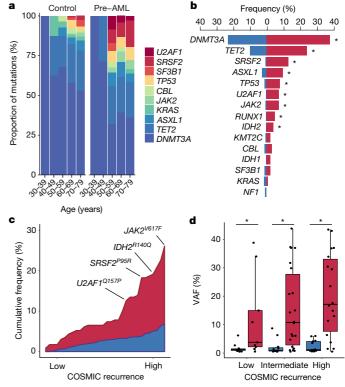

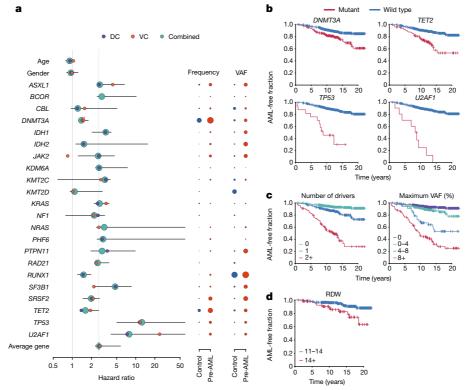

Fig. 2 | Accumulation of specific recurrent AML mutations in healthy individuals at a young age is associated with progression to AML. a, Relative frequency of mutations in the indicated genes according to age group for pre-AML cases and controls. b, Proportion of pre-AML cases (red) and controls (blue) who had ARCH-PD mutations in recurrently mutated genes. \*P < 0.05, Fisher's exact test with Bonferroni multiple testing correction. c, The cumulative frequency of recurrent AML mutations (reported in >5 specimens in COSMIC) in pre-AML cases and controls. ARCH-PD mutations are ranked from left to right along the x axis from low to high recurrence. d, VAF of recurrent mutations in pre-AML cases and controls. Low, intermediate and highly recurrent COSMIC mutations are defined as those reported in 5-19 samples, 20-300 samples and >300 samples, respectively. Box plots indicate median, first and third quartiles and  $1.5 \times$  interquartile range. \**P* < 0.05, two-sided Wilcoxon rank-sum test with Bonferroni multiple testing correction. All panels show data for n = 800 unique individuals.

In line with previous reports<sup>5,6</sup>, we found that DNMT3A and TET2 were the most commonly mutated genes in both groups (Fig. 2b). We could not identify any canonical NPM1 mutations nor any FLT3internal tandem duplication mutations, consistent with these arising late in leukaemogenesis<sup>10,13</sup>. Recurrent CEBPA mutations, which are implicated in around 10% of de novo AML<sup>14</sup>, were also absent, suggesting that driver events in this gene may also be late events in AML evolution. In order to quantify the effect of different mutations on the likelihood of progression to AML, we ranked ARCH-PD mutations based on the number of times that they have been reported in Catalogue of Somatic Mutations in Cancer (COSMIC) database among individuals with haematological malignancies<sup>15</sup>. We found that mutations that are highly recurrent in cancer specimens were more common in pre-AML cases than in controls with ARCH-PD, whereas driver events in the controls tended to affect loci that are less frequently mutated in haematological malignancies and occurred at significantly lower VAF (Fig. 2c, d). Overall, these findings demonstrate notable differences in the mutational landscape of ARCH and pre-AML. Moreover, this work, in conjunction with recent insights into the origins of AML relapse<sup>16</sup>, suggests that AML progression typically occurs over many years through clonal evolution of preleukaemic HSPCs before acquisition of late mutations leads to overt malignant transformation.

19 JULY 2018 | VOL 559 | NATURE | 401

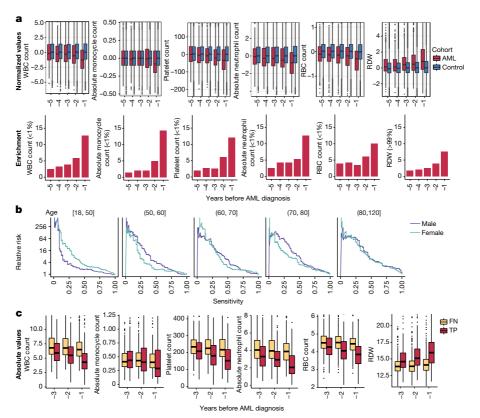

**Fig. 3** | **Model of future risk of AML. a**, Forest plot of the risk of AML. Purple, orange and green circles indicate hazard ratios for the discovery (DC), validation (VC) and combined cohort, respectively. The horizontal lines denote 95% confidence intervals for the combined cohort. For each gene, the indicated hazard ratio applies to the 10-year risk of AML development conferred by each 5% increase in mutation VAF. The green vertical line indicates the mean hazard ratio across all genes. The hazard ratio for *RUNX1* must be interpreted with caution owing to the relatively high prevalence of deleterious germline variants in this gene, which may not be readily distinguishable from somatic mutations in unmatched

On the basis of these findings, we next developed an approach to quantify the relative contributions of driver mutations and clone sizes to the risk of progressing to AML. We tested different regularised logistic and Cox proportional hazards regression approaches, which achieved similar performance in both the discovery cohort (concordance (*C*) =  $0.77 \pm 0.03$ ) and the validation cohort (*C* =  $0.84 \pm 0.05$ ; Extended Data Figs. 3, 4 and Supplementary Table 3). Models that were only trained on data from the discovery or validation cohort had similar coefficients (Fig. 3a). We therefore combined the datasets for a more accurate analysis of the contributions of mutations in individual genes to risk ( $C = 0.77 \pm 0.05$ ; area under curve, 0.79; Supplementary Table 3). Quantitatively, we found that driver mutations in most genes conferred an approximately twofold increased risk of developing AML per 5% increase in clone size (Fig. 3a and Supplementary Table 3). Notable exceptions to this trend are the most frequently mutated ARCH genes, DNMT3A and TET2, which confer a lower risk of progression to AML (Fig. 3a, b and Supplementary Table 3). By contrast, a larger effect size was apparent for TP53 (hazard ratio, 12.5; 95% confidence interval, 5.0-160.5) and U2AF1 (hazard ratio, 7.9; 95% confidence interval, 4.1-192.2) mutations (Fig. 3a, b). However, we note that other ARCH-PD genes, such as SRSF2, can contribute a similar relative risk owing to their presence at a higher VAF in pre-AML cases (Fig. 3a, Extended Data Fig. 5a and Supplementary Note). Of note, mutations in TP53 and spliceosome genes (including U2AF1) are also associated with a poorer prognosis in AML<sup>14</sup>. Because the effect of each ARCH-PD mutation is deleterious and the effect of multiple mutations that are present in the same individual is multiplicative, a higher number of mutations is predicted to increase the risk of progression to AML (Fig. 3c). Similarly,

sequencing assays (see Methods). The proportion of individuals with mutations in each gene and the average VAF are indicated to the right of the forest plot; red and blue circles represent pre-AML cases and controls, respectively, with circle sizes scaled to reflect mutation frequency and VAF. **b**-**d**, Kaplan–Meier curves of AML-free survival, defined as the time between sample collection and AML diagnosis, death or last follow-up. Survival curves are stratified according to mutation status for selected genes (**b**), number of driver mutations per individual and largest clone detected (**c**) and RDW (**d**). Data for n = 796 unique individuals (**a**-**c**); n = 299 individuals for whom RDW measurements were available (**d**).

the size of the largest driver clone was also strongly associated with the risk of progression to AML, in agreement with the risk of individual mutations generally being proportional to VAF (Fig. 3c). Collectively, although the VAF and the number of mutations confer much of the predictive value, this model does demonstrate distinct gene-level risk factors, and is able to quantify the cumulative impact of multiple mutations and clonal size on the likelihood of progression to AML.

Although our predictive model performs well in identifying those at risk of developing AML in our experimental cohorts, AML incidence rates in the general population are low  $(4:100,000)^1$ , and thus millions of individuals would need to be screened to identify the few pre-AML cases, with many false positives. We therefore sought to determine whether routinely available clinical information could improve prediction accuracy or identify a high-risk population for targeted genetic screening. We first analysed complete blood count and biochemistry data that were available for 37 of the pre-AML cases and 262 controls. As reported previously<sup>5,10,17</sup>, ARCH-PD was overwhelmingly associated with normal blood counts and this was also the case for pre-AML cases, indicating that these did not represent undiagnosed myelodysplastic syndrome<sup>18</sup>. We identified a significant association between higher red blood cell distribution width (RDW) and risk of progression to AML (P = 0.0016, Wald test with Bonferroni multiple-testing correction, Fig. 3d). Although traditionally used in the evaluation of anaemia, raised RDW has been correlated with inflammation, ineffective erythropoiesis, cardiovascular disease and adverse outcomes in several inflammatory and malignant conditions<sup>19</sup>. The correlation between RDW and risk of AML development remained highly significant when controls without ARCH-PD were excluded

**Fig. 4** | **Increased risk of AML development inferred from electronic health records. a**, Box plot of normalized laboratory measurements. Increased RDW, reduction in monocyte, platelet, red blood cell (RBC) and white blood cell (WBC) counts (top) show a high association (bottom) with a higher risk of AML development and differed at least a year before

AML diagnosis. **b**, Model performance stratification by age and gender. Age ranges are indicated above each graph. **c**, Absolute laboratory values for true positive (TP) and false negative (FN) predictions. Box plots indicate median, first and third quartiles and  $1.5 \times$  interquartile range.

from the analysis ( $P = 3.5 \times 10^{-6}$ , Wald test with Bonferroni multiple testing correction; Extended Data Fig. 5b). Higher RDW has previously been associated with ARCH and overall mortality<sup>5</sup>, but has never been shown to distinguish ARCH from pre-leukaemia. In order to verify RDW as a predictive factor and determine whether additional clinical parameters are associated with risk of AML development, we studied the Clalit database<sup>20</sup>, which contains electronic health records that include an average of 3.45 million individuals per year and data that were collected over a 15-year period<sup>21</sup>. We identified 875 cases with AML using stringent criteria based on diagnostic codes and treatment records (Extended Data Fig. 6 and Supplementary Table 4). Analysis of RDW trends revealed significantly raised measurements several years before AML diagnosis relative to age and sex-matched controls (Fig. 4a). Additional parameters that correlated with risk of AML development included reductions in monocyte, platelet, red blood cell and white blood cell counts, albeit usually remaining above the thresholds for clinically relevant cytopenias<sup>18</sup> (Fig. 4a and Extended Data Fig. 7). These findings suggest that evolving de novo AML may sometimes have a considerable prodrome with subtle but discernible clinical manifestations. We next applied a machine-learning approach to construct an AML prediction model based entirely on variables that are routinely documented in electronic health records (Extended Data Fig. 8 and Supplementary Table 4). This model was able to predict AML 6-12 months before diagnosis with a sensitivity of 25.7% and overall specificity of 98.2%. The model performed consistently across different age groups with an increased relative risk of 28 and 24 for males and females, respectively, between the age of 60 and 70 years (Fig. 4b). To better understand which patients are most likely to be accurately classified by this model, we compared absolute laboratory values for true positives and false negatives. We found that 35.5% of false-negative predictions were for patients for whom infrequent blood count data were available (Extended Data Fig. 9). Some of the true-positive cases

had mildly abnormal blood counts that would not initiate a diagnostic work-up (Fig. 4c), and cytopenias that would be compatible with undiagnosed myelodysplastic syndrome<sup>18</sup> were uncommon.

Collectively, our findings provide new insights into the pre-clinical evolution of AML and support the hypothesis that individuals at high risk of AML development can be identified years before they develop overt disease. To this end, we present two distinct models for the prediction of de novo AML: one based on somatic point mutations and the other on routinely documented clinical information. We find that basic clinical and laboratory data can identify a high-risk subgroup 6-12 months before AML presentation, while genetic information can identify a substantial fraction of cases several years to more than a decade before diagnosis. By characterizing features that distinguish benign ARCH from pre-leukaemia, our models give valuable insights into leukaemogenesis. It is evident from the current study, together with our recent analysis of mutation acquisition from pre-leukaemic development through to relapse<sup>16</sup>, that long-term pre-leukaemic HSPCs frequently carry mutations and undergo considerable clonal expansion while retaining differentiation capacity for years before AML diagnosis. Furthermore, it is clear that some mutations, particularly those affecting TP53 and U2AF1, impart a relatively high risk of subsequent AML, whereas mutations in other genes, for example DNMT3A and TET2, confer a lesser risk of malignant transformation. Previous studies suggest that oncogenic mutations in TP53 and spliceosome genes confer little or no competitive advantage in the absence of particular selective pressures<sup>11,22</sup>, indicating that cell-extrinsic factors may be important determinants of clonal trajectory.

Cancer predictive models have enabled successful early detection and intervention programmes for several solid tumours<sup>23–25</sup>. However, screening tests are unavailable for the sub-clinical stages of most haematological malignancies. Our study provides proof-of-concept for the feasibility of early detection of healthy individuals at high risk

of developing AML, and is a first step in the design of future clinical studies to investigate the potential benefits of early interventions in this deadly disease. However, the infrequency of AML necessitates that future screening tests provide high sensitivity and specificity. Our findings suggest that basic clinical data may identify a higher risk population that might benefit from targeted genetic screening. Equally, combining clinical and genetic information in a single model and including structural driver events is likely to improve model accuracy further. Nevertheless, establishing the utility of such a tandem approach will require extensive clinical and genetic analysis on the same population cohort, in a prospective setting. Furthermore, ARCH is associated with several non-malignant conditions<sup>4,5</sup>, and may have a causal role in cardiovascular disease<sup>26,27</sup>. Therefore, genetic testing for ARCH may also prove useful in the management of common age-related diseases. Moreover, this study has broader implications for cancer screening and early intervention beyond AML. Advances in sequencing technologies have revealed a remarkable degree of somatic genetic diversity in normal ageing tissues, often characterized by the presence of clones that have canonical oncogenic mutations<sup>28</sup>. The degree to which clones at high risk of malignant transformation can be reliably distinguished from their indolent counterparts is an important biological question with compelling clinical ramifications. Understanding the selective pressures and cell-intrinsic mechanisms governing clonal fate is the next important step in developing strategies to predict and prevent progression to overt malignancy.

**Reviewer information** *Nature* thanks R. Levine, P. Van Loo and the other anonymous reviewer(s) for their contribution to the peer review of this work.

Author contributions S.W.K.N., O.W., N.M.C. and E.N. contributed equally to the work. S.A. performed error-corrected sequencing, analysed sequencing data, performed statistical analyses, contributed to genetic predictive model derivation and wrote the manuscript. G.C. performed variant calling, statistical analyses, derived genetic predictive models and wrote the manuscript. M.G., S.W.K.N., O.W. and R.C. derived genetic predictive models. N.M.C., E.N. and N.B. derived the clinical prediction model. P.C.Z., Z.Z., I.C., K.N., C.L., C.H., D.H., F.M., J.E., J.K.M., D.P., L.T., P.K., S.V.B. and A.Br. and A.Ba. provided sequencing and technical support and enabled sample acquisition. L.H., Y.S., T.T.W., T.J.P., K.R and D.J. provided bioinformatics support. R.L., S.H., M.J., K.M.B., A.Kr. and N.J.W. enabled sample acquisition, clinical data curation and/or provided clinical expertise. D.S., J.D.M., P.A., E.S., S.B., P.Be., M.D.M and I.M. contributed to data analysis and interpretation. P.J.C. and E.P. contributed to data interpretation and designed the targeted sequencing assay for the validation cohort. J.C.Y.W. revised the manuscript. J.R.Q., A.Ka., C.L.V., A.T., E.S.-F., J.M.H., R.C.T., R.T., G.M., H.B., S.Pa., R.K., S.S., S.Po., N.J.W., N.S., K.-T.K., M.F., J.M.K., E.R., P.V. and R.V. enabled sample acquisition (EPIC). A.T. and R.D.B. analysed Clalit data and derived the clinical prediction model. M.G. derived predictive genetic models, contributed to sequencing data analysis and manuscript writing. J.E.D. contributed to funding applications, study supervision and manuscript writing. P.Br. supervised sample acquisition from all EPIC centres. G.S.V. and L.I.S designed and supervised all aspects of the study and wrote the manuscript.

#### **METHODS**

**Data reporting.** No statistical methods were used to predetermine sample size. The experiments were not randomized and the investigators were not blinded to allocation during experiments and outcome assessment.

**Study participants.** Samples for both the discovery and validation cohort were obtained from participants in the EPIC study<sup>29</sup>. All relevant ethical regulations were followed. Written informed consent was obtained from all participants in accordance with the Declaration of Helsinki and protocols were approved by the relevant ethics committees (IARC Ethics Committee approval #14-31, the Weizmann Institute of Science Ethics board approval #60-1 and East of England-Cambridgeshire and Hertfordshire Research Ethics Committee reference number 98CN01). Patients with AML were identified based on the following ICD9 codes: 9861/3, 9860/3, 9801/3, 9866/3, 9891/3, 9867/3, 9874/3, 9840/3, 9872/3, 9895/3, 9873/3, which included only cases of de novo AML, and no secondary AML. All patients provided peripheral blood samples for which the buffy coat fractions were separated and aliquoted for long-term storage in liquid nitrogen before DNA extraction.

*Discovery cohort.* In total, 509 DNA samples were collected from individuals upon enrolment into the EPIC study between 1993 and 1998 across 17 different centres<sup>29</sup> (Supplementary Table 1). Altogether, 95 individuals who developed AML an average of 6.3 years (interquartile range (IQR) = 4.8 years) after the sample was collected were included in the pre-AML group. For the control group, 414 age- and gender-matched individuals were selected, as they did not develop any haematological disorders during the average follow-up period of 11.6 years (IQR = 2.1 years). The median age at recruitment was 56.7 years (range, 36.08–74.42). In order to minimize any possible demographic biases, an approximate 1:4.5 pre-AML to control ratio was maintained across the different centres.

Validation cohort. Samples were obtained from individuals enrolled in the EPIC-Norfolk longitudinal cohort study between 1994 and 2010. Samples and clinical metadata were available from 37 patients with AML (of which 8 were already included in the discovery cohort) and 262 age- and gender-matched controls without a history of cancer or any haematological conditions. The average time between the first blood sampling and AML diagnosis was 10.5 years (IQR = 8.3 years). The average follow-up period for the control cohort was 17.5 years (IQR = 3.8). For 12 individuals in the pre-AML cohort, 2–3 blood specimens were available, taken a median of 3.4 years apart. Of the 262 controls, 141 had multiple blood samples available, spanning a median of 10.5 years. Blood counts and other clinical parameters were available for all study participants (Supplementary Table 1).

**Targeted sequencing.** *Discovery cohort sequencing.* Targeted deep sequencing was performed using error-corrected sequencing as follows.

Shearing of genomic DNA, preparation of pre-capture sequencing libraries, hybridization-based enrichment, assessment of the libraries quality and enrichment following hybridization were performed as previously described<sup>30</sup>. In brief, 100 ng of genomic DNA was sheared before library construction (KAPA Hyper Prep Kit KK8504, Kapa Biosystems) with a Covaris E220 instrument using the recommended settings for 250-bp fragments. Following end repair and A-tailing, adaptor ligation was performed using 100-fold molar excess of Molecular Index Adaptor. Library clean-up was performed with Agencourt AMPure XP beads (Beckman-Coulter) and the ligated fragments were then amplified for eight cycles using 0.5  $\mu$ M Illumina universal and indexing primers.

Targeted capture was carried out on pools containing three indexed libraries. Each pool of adaptor-ligated DNA was combined with 5  $\mu l$  of 1 mg ml^{-1} Cot-I DNA (Invitrogen), and 1 nmol each of xGEN Universal Blocking Oligo, TS-p5, and xGen Universal Blocking Oligo, TS-p7 (8 nucleotides). The mixture was dried using a SpeedVac and then re-suspended in 1.1 µl water, 8.5 µl NimbleGen  $2 \times$  hybridization buffer and  $3.4 \,\mu$ l NimbleGen hybridization component A. The mixture was heat denatured at 95 °C for 10 min before addition of 4  $\mu l$  of xGen Lockdown Probes (xGen AML Cancer Panel v.1.0, 3 pmol). Each pool was then hybridized at 47 °C for 72 h. Washing and recovery of the captured DNA was performed according to the manufacturer's specifications. In brief, 100  $\mu l$  of clean streptavidin beads was added to each capture. Following separation and removal of the supernatant using a magnet, 200  $\mu$ l 1imes Stringent Wash Buffer was added and the reaction was incubated at 65 °C for 5 min. The supernatant containing unbound DNA was removed before repeating the high stringency wash one additional time. Then, the bound DNA was washed as follows: (1) 200  $\mu l$  1× Wash Buffer I and separation of the supernatants by magnetic separation; (2) 200  $\mu l$  1  $\times$  Wash Buffer II after magnetic separation; (3) 200  $\mu$ l 1 $\times$  Wash Buffer III and removal of the supernatants using magnetic separation. The captured DNA on beads was resuspended in 40 µl of Nuclease-Free water before dividing the total volume into two PCR tubes and subjecting the libraries to 10 cycles of post-capture amplification (manufacturer-recommended conditions; Kapa Biosystems). Before sequencing, libraries were spiked with 2% PhiX.

Validation cohort sequencing. Targeted sequencing was performed using a custom complementary RNA bait set (SureSelect, Agilent, ELID 0537771) designed

complementary to all coding exons of 111 genes that have been implicated in myeloid leukaemogenesis (Extended Data Table 1). Genomic DNA was extracted from peripheral whole blood and sheared using the Covaris M220. Equimolar pools of 10 libraries were prepared and sequenced on the Illumina HiSeq 2000 using 75-bp paired-end sequencing as per Illumina and Agilent SureSelect protocols.

Variant calling. Discovery cohort variant calling and error correction. The 126-bp paired-end reads sequencing data from the Illumina platform were converted to FASTQ format, the 2-bp molecular barcode information at each read of the pair was trimmed and was written in the reads' name. The thymine nucleotide required for ligation was removed from the sequences. Burrows-Wheeler aligner (BWA-mem)<sup>31</sup> was used for alignment of the processed FASTQ files to the reference hg19 genome, after realignment of insertions and deletions (indels) using GATK<sup>32</sup>. An in-house algorithm was written to collapse read families that share the same molecular barcode sequence, the left-most genomic position of where each read of the pair maps to the reference and the CIGAR string. Families that consisted of at least two reads were used to generate consensus reads and a consensus base was called when there was at least 70% agreement. When a consensus base was called, it was assigned with the maximum base quality score observed in its corresponding pre-collapsed reads. Furthermore, when possible, duplex reads<sup>33</sup> were generated from two consensus reads, from a singleton read and a consensus read, or from two singleton reads. For each sequenced sample, we generated two BAM files, called BAM1 and BAM2. BAM1 consisted of duplex reads, consensus reads and singleton reads, thereby including some error-corrected and non-error corrected reads, while still containing all the genomic information encoded in the data in the form of unique DNA molecules. BAM2 consisted of duplex reads and consensus reads but not singleton reads. Both files were then analysed to detect single nucleotide variants (SNVs) and small indels using Varscan2<sup>34</sup>. To further remove sequencing artefacts and improve sensitivity, we applied a two-step polishing statistical approach that models the error rate for each sequenced genomic position. For both steps, BAM1 was used and all samples except the sample that was investigated were included for error rate modelling. At step one, as previously described<sup>30</sup>, the error rates were modelled by fitting Weibull distribution curves to the non-reference allele fractions. SNVs with allele fractions that were statistically distinguishable from the background error rates (P = 0) were further analysed. At step 2, the coverage of the non-reference allele fractions was considered using linear line fitting that describes the negative correlation that exist between the log(non-reference allele fraction) and the corresponding log(coverage) values. This allowed us to estimate different error rates at different coverage depths. Because indel errors are rare and cannot be appropriately modelled by the same statistical framework, they were called using barcode-mediated error correction alone. At least 10 consensus reads, 5 supporting reads on the forward strand, 5 supporting reads on the reverse strand and 2 duplex reads were required to call an indel. Additional post-processing steps applied to data from both the discovery cohort and validation cohort are detailed in 'Additional post-processing filters applied to discovery and validation cohort data'. Variants were annotated using Annovar<sup>35</sup>. Validation cohort variant calling. Sequencing reads were aligned to the reference genome (GRCh37d5) using the Burrows-Wheeler aligner (BWA-aln)<sup>31</sup>. Unmapped reads, PCR duplicates and reads mapping to regions outside the target regions (merged exonic regions and 10 bp either side of each exon) were excluded from analysis. Sequencing depth at each base was assessed using Bedtools coverage v.2.24.036

Somatic SNVs were called using shearwater, an algorithm developed for detecting subclonal mutations in deep-sequencing experiments (https://github. com/gerstung-lab/deepSNV v.1.21.5)<sup>37-39</sup> considering only reads with minimum nucleotide and mapping quality of 25 and 40, respectively. This algorithm models the error rate at individual loci using information from multiple unrelated samples. Additionally, allele counts at the recurrent AML mutation hotspots listed in 'Curation of oncogenic variants' were generated using an in-house script (https://github.com/cancerit/alleleCount) and manually inspected in the Jbrowse genome browser<sup>40</sup>. To further complement our SNV calling approach, we applied an extensively validated in-house version of CaVEMan v.1.11.2 (Cancer variants through expectation maximization)<sup>41</sup>. CaVEMan compares sequencing reads between study and nominated normal samples and uses a naive Bayesian model and expectation-maximization approach to calculate the probability of a somatic variant at each base (https://github.com/cancerit/CaVEMan).

Post-processing filters required that the following criteria were met for CaVEMan to call a somatic substitution. (1) If coverage of the mutant allele was less than 8, at least one mutant allele was detected in the first two-thirds of the read. (2) Less than 3% of the mutant alleles with base quality  $\geq$ 15 were found in the nominated normal sample. (3) Mean mapping quality of the mutant allele reads was  $\geq$ 21. (4) The mutation does not fall in a simple repeat or centromeric region. (5) Fewer than 10% of the reads covering the position contained an indel according to mapping. (6) Less than 80% of the reads report the mutant allele at the same read position. (7) At least a third of the reads calling the variant had a base quality

of 25 or higher. (8) Not all mutant alleles reported in the second half of the read. (9) Position does not fall within a germline insertion or deletion.

The following additional post-processing criteria were applied to all SNV calls. (1) Minimum VAF = 0.5% with a minimum of five bidirectional calls reporting the mutant allele (with at least two reads in forward and reverse directions). (2) No indel called within a read length (75 bp) of the putative substitution.

Small indels were sought using two complementary bioinformatics approaches. First, an in-house version of Pindel v.2.2<sup>42</sup> (https://github.com/cancerit/cgpPindel) was applied. We additionally used the aforementioned deepSNV algorithm in order to increase sensitivity for indels present at low VAF. VAF correction was performed using an in-house script (https://github.com/cancerit/vafCorrect).

Post-processing filters required that the following criteria were met for a variant to be called. (1) A minimum of five reads supporting the variant with a minimum of two reads in each direction. For Pindel, the total read count was based on the union of the BWA and Pindel reads reporting the mutant allele. (2) VAF  $\geq$  0.5%. (3) Variant not present within an unmatched normal panel of approximately 400 samples. (4) No reads supporting the variant identified in the nominated normal sample.

Mutations were annotated according to ENSEMBL v.58 using VAGrENT<sup>43</sup> for transcript and protein effects (https://github.com/cancerit/VAGrENT) and Annovar<sup>35</sup> for additional functional annotation.

Additional post-processing filters applied to discovery and validation cohort data. The following variants were flagged for additional inspection for potential artefacts, germline contamination or index-jumping event. (1) Any mutant allele reported within 75 bp of another variant. (2) Any mutant allele with a population allele frequency >1 in 1,000 according to any of five large polymorphism databases (ExAC, 1000 Genomes Project, ESP6500, CG46 and Kaviar) that is not a canonical hotspot driver mutation with COSMIC recurrence >100. (3) Mutations that were present in >10% of the control cohort but not recurrent in COSMIC were flagged as potential germline variants or sequencing artefacts. (4) As artefactual indels tend to be recurrent, any indels occurring in >2 samples were flagged as for additional inspection.

**Curation of oncogenic variants.** Putative oncogenic variants were identified according to evidence for functional relevance in AML as previously described and used to define ARCH-PD<sup>14</sup>.

Variants were annotated as likely driver events if they fulfilled any of the following criteria. (1) Truncating mutations (nonsense, essential splice site or frameshift indel) in the following genes implicated in AML pathogenesis by loss-of-function: NF1, DNMT3A, TET2, IKZF1, RAD21, WT1, KMT2D, SH2B3, TP53, CEBPA, ASXL1, RUNX1, BCOR, KDM6A, STAG2, PHF6 and KMT2C. (2) Truncating variants in CALR exon 9. (3) JAK2<sup>V617F</sup>. (4) FLT3 internal tandem duplication. (5) Nonsynonymous variants at the following hotspot residues: CBL E366, L380, C384, C404, R420 and C396; DNMT3A R882; FLT3 D835; IDH1 R132; IDH2 R172 and R140; KIT W557, V559 and D816; KRAS A146, Q61, G13 and G12; MPL W515; NRAS Q61, G12 and G13; SF3B1 K700 and K666; SRSF2 P95; U2AF1 Q157, R156 and S34. (6) Non-synonymous variants reported at least 10 times in COSMIC with VAF <42% and population allele frequency <0.003. (7) Non-synonymous variants clustering within a functionally validated locus or within four amino acids of a hotspot variant with population allele frequency <0.003 and VAF <42%. (8) Non-synonymous variants reported in COSMIC >100 times with population allele frequency < 0.003 regardless of VAF.

Our driver curation strategy inevitably runs a small risk of including germline variants in familial AML genes. We feel that in the real world, where a matched constitutional DNA sample would be unavailable, this is the best approach.

**Statistical analysis.** All statistical analyses were performed in the R statistical programming environment. A two-sided Wilcoxon rank-sum test was used to assign significance level for differences in the median number of somatic mutations among the pre-AML and control groups, the median VAF of mutations among groups. and the age of individuals with spliceosome mutations. Fisher's exact test was used to assess the significance of differences in the prevalence of ARCH among the groups and spliceosome mutations in the pre-AML group.

**Predictive modelling.** *Cox proportional hazards model with random effects.* We used a Cox proportional hazards regression to model AML progression-free survival as previously described<sup>14,38</sup>. We used random effects for the Cox proportional hazards model in the CoxHD R package (http://github.com/gerstung-lab/CoxHD). A key strength of this approach is the ability to include many variables in one model while shrinking estimated effects for parameters with weak support in the data, thus controlling for overfitting. We used weighting to minimize the biases introduced by the artificial case–control ratio<sup>44,45</sup> and calculated hazard ratios relative to the (approximate) true cumulative incidence of about 1–3/1,000 in the given age range over a follow up of 10–20 years. The observed driver mutation frequency and VAF in pre-AML cases closely resembled values expected based on the estimated risks, indicating that risk model and driver prevalence are well aligned (Extended Data Fig. 4). Full details of model derivation and comparisons

with alternative methods are included in the accompanying code (Supplementary Note, also available at https://github.com/gerstung-lab/preAML). In brief, variables comprised age, gender and the VAF of putative driver mutations (see 'Curation of oncogenic variants' for details of variant curation). We performed agnostic imputation of missing variables by mean and linear rescaling of gene variables by a power of 10 to a magnitude of 1. The model was first trained separately on the discovery cohort and validation cohort. For each of these two models, we evaluated the following measures of predictive accuracy before and after leave-one-out cross-validation (LOOCV): concordance (C)<sup>46</sup> and time-dependent area under the receiver-operating characteristic curve (AUC)<sup>47</sup>. The models trained on the validation and discovery cohorts were then cross-validated using the data from the other cohort. In view of the cross-validation results and close correlation between coefficients (Supplementary Table 3), we derived a model on the combined cohorts using both cohorts in order to achieve greater accuracy on the individual effects. Confidence intervals were calculated using 100 bootstrap samples. The coefficients and performance metrics for each iteration of the model are included in Supplementary Table 3.

Concordance measures were obtained using the survConcordance() function implemented in the survival R package<sup>45</sup>. Dynamic AUC was calculated with AUC.uno() implemented in the survAUC package. Time-independent AUCs were calculated using the performance function implemented in the ROCR package. The expected incidence of AML was calculated from the UK office of national statistics, available at http://www.cancerresearchuk.org/health-professional/ cancer-statistics/statistics-by-cancer-type/leukaemia-aml/incidence. All-cause mortality data was obtained from the office of national statistics (https://www.ons. gov.uk/peoplepopulationandcommunity/birthsdeathsandmarriages/lifeexpectancies/datasets/nationallifetablesunitedkingdomreferencetables).

*Ridge-regularized logistic regression.* Using the same covariates as in 'Cox proportional hazards model with random effects', we fitted a ridge-regularized logistic regression model to dichotomised outcome data. While logistic regression is a common choice for case-control analyses, a downside of this approach is the inability to explicitly use time-dependent covariates. The penalty parameter was chosen using LOOCV on the full cohort; this value was then used on the discovery cohort and validation cohort to yield the same scaling of coefficients. Confidence intervals were calculated using 100 bootstrap samples. Fitting was performed using the glmnet R package. AUC as the primary performance metric was calculated using the ROCR R package.

Additional regression models. Two alternative predictive models were developed. Model 1 performs logistic-regression-based predictions using four types of features: gender, age at blood sampling, the sum of the VAFs ARCH-PD reported in COSMIC v.80 to be recurrent (at least two case reports in haematopoietic and lymphoid tissues) and somatic mutation burden of selected genes, where each gene was represented by the sum of the VAFs corresponding to ARCH-PD mutations in that gene. We measured the predictive performance of each gene via the AUC obtained in a fivefold cross-validation when using only the gene as a predictive feature, and only retained genes with AUC > 55% in the final model.

For model 2 we applied LASSO regression as implemented in the glmnet R package, while enabling LOOCV to fit a Cox regression model. A minimal subset of ARCH-PD variants was selected for which the respective weighted combined VAFs were highly predictive of AML development in the training set. Scores were calculated for each patient as a linear combination of VAF of mutations weighted by regression coefficients that were estimated from the training data. As most scores were zero in the training subset, non-zero scores were discretized to take on a value of 1 that corresponds to AML prediction.

Models 1 and 2 were trained on the discovery cohort and tested for their association with AML development using the validation cohort data. Survival analysis was performed using the Kaplan–Meier and Cox proportional hazards models. Wald's test was used to evaluate the significance of hazard ratios. Logistic regression models were used with the positive predictive value metric to determine the ability of various mutations and other patient parameters to predict AML development. The rms R package was used for logistic regression analysis, and the pROC 1.8 R package was used for receiver-operating characteristic curve analysis.

**AML-predictive model based on electronic health records.** *Clalit database.* The Clalit database includes information from patients covered by the Clalit health services in Israel<sup>20</sup> during the years 2002–2017. The Clalit training-set data, contains the electronic health records (EHR) of 3.45 million individuals per year on average. All data was anonymized through hashing of personal identifiers and addresses and randomization of dates by sampling a random number of weeks for each patient and adding it to all dates in the patient diagnoses, laboratory and medication records. This approach maintained differential data analysis per patient. Diagnoses codes were acquired from both primary care and hospitalization records, and were mapped to the ICD-9 coding system. Laboratory records were normalized for age and gender by subtracting raw test values from the median

levels observed among all test values with matching gender and age (using a bin size of five years). We observed some chronological biases in laboratory ranges, but avoid normalizing these and instead insured case and controls are matched for chronological distributions.

Defining AML cases. We screened for all active patients (18 < age < 100) who were diagnosed with AML (ICD-9 code 205.0\*) between the years 2003 and 2016. We then excluded cases based on the following criteria. (1) We excluded patients with prior myeloid malignancies to omit secondary AML, consistent with the case selection for the genetic model. The following diagnosis were excluded if documented within five years before the diagnosis of AML: essential thrombocythemia (ICD-9 238.71), low-grade myelodysplastic syndrome (MDS) (ICD-9 238.72); high-grade MDS lesions (ICD-9 238.73); MDS with 5q deletion (ICD-9 238.74); MDS, unspecified (ICD-9 238.75); polycythemia vera (ICD-9 238.4); myelofibrosis (ICD-9 289.83); chronic myelomonocytic leukaemia (ICD-9 206.10-206.22).

(2) Patients that had any procedures performed on bone marrow or spleen (ICD-10 code Z41) in the five-year period before first mention of AML diagnosis code in their record. These patients were presumed to have an inaccurate AML diagnosis date or misdiagnosis recorded.

(3) Patients that received medications suggestive of an alternative diagnosis of chronic myeloid leukaemia, lymphoid malignancy or acute promyelocytic leukaemia (APL). At any time before diagnosis: imatinib, dasatinib, anagrelide, hydroxycarbamide, asparaginase, pegaspargase or arsenic trioxide. At any time after diagnosis: imatinib, dasatinib, methotrexate, tretinoin or arsenic trioxide. At any time after diagnosis, along with any acute lymphoblastic leukaemia diagnosis (ICD-9 204) or more than single dose: mercaptopurine. APL cases were excluded as early diagnosis of APL will most probably not change its outcome, as treatment is successful already.

(4) Patients without a hospitalization record within three months before or after the onset diagnosis. This parameter was used as it is unlikely that a patient with AML will not be hospitalized close to diagnosis. This filter reduced false-positive cases and better defined the onset date.

We refined the estimated time of onset using the earliest time at which any of the following diagnosis appeared in the patient's history: amyloidosis (ICD-9 277.3), lymphoid leukaemia (ICD-9 204), myeloid leukaemia (ICD-9 205), leukaemia of unspecified cell type (ICD-9 208).

This strategy retained 875 AML cases in the training set for further analysis. These were further validated by manual expert inspection of the complete records of 8% of the cases.

To define the control set, we included all Clalit individuals that were not cases. Since our analysis was aggregating data from a historical time window of 15 years, we associated each control with a randomized time point for evaluation. Using this approach, both cases and controls represented a specific time point in the historical record of a patient, with matching calendric, age and gender distributions. Through this strategy 5,238,528 controls were used.

Defining features for construction of a predictive a score. We extracted the following features for discriminative analysis of cases and controls (this procedure was applied repeatedly in cross-validation as discussed below). (1) Age (in years) at time point. (2) Gender. (3) Laboratory features. Out of 2,770 different types of laboratory tests, we selected the top 50 most frequent laboratory tests (Supplementary Table 4). For each laboratory measurement, we used median age- and gendernormalized test values per patient in three time windows for 6–12 months before onset, 1-2 years before onset and 2-3 years before onset. In addition, we compute the slope of the normalized laboratory measurements for the 6-12 month time window using a linear regression model. (4) Diagnosis features. Of the 1780 different major ICD-9 diagnosis codes, we selected only diagnoses that were previously observed in at least 10 different cases and have an increased relative risk for AML >twofold (as observed in the training set, Supplementary Table 4). For each diagnosis code, we mark whether it appeared in each of the patients in time intervals of 6 months to 3 years, and 3-5 years before onset. (5) BMI features. For each patient in the cohort, we extracted median BMI, weight and height as measured in time intervals of 6 months to 2 years, and 2-3 years before onset.

Gradient boosting. We used the R package xgboost to infer parameters for a classifier given cases and controls. Objective was set to binary:logistic, the evaluation metric to AUC. We set nrounds = 5000, eta = 0.001, gamma = 0.1, lambda = 0.01, alpha = 0.01, max\_depth = 6, min\_child\_weight = 2, subsample = 0.7 and colsample\_bytree = 0.7. The boosting algorithm reports a function f that computes a predictive score given the features. Given a threshold T the expression f(patient features) > T defines a classifier. To standardise thresholds we estimate quantiles for the scores on the training set T(p) = quantile(f(train), p) and define the classifier for specificity level *p* as f(patient features) > T(p) (Supplementary Table 4). Cross-validation and relative risk evaluation. To evaluate the predictive value of the classification scheme while considering the strong age and gender biases in the incidence of AML, we performed fivefold cross-validation after splitting the

cases and controls into five age- and gender-matched groups. For each fold, we sampled 100,000 controls and combined with the cases, constructed the feature set and trained the model. The model was then tested on the fold cases along with 200,000 sampled controls. We used standardized classifier parameters and standardized thresholds that were inferred based on each training set to generate a series of classifications on each test set and merged these based on the control quantiles in the test as described above. Given a threshold p to define high and low prediction score, we counted for each bin *b* that defines a patient in a specific age (<40, 40-50, 50-60, 60-70, 70-80, >80) and gender group: the number of cases in bin  $b (N^{b}_{case})$  and the number of controls in bin  $b (N^{b}_{control})$  where  $N^{b}$  is the number of patients in bin b (entire database minus recall controls that are only a sample of the cohort).  $N^{b}$ (case, high score) =  $N^{b}_{TP}$  indicates the number of true positives (TP);  $N^b$ (case, low score) =  $N^b_{FN}$  indicates the number of false negatives (FN);  $N^{b}$ (control, high score) =  $N^{b}_{FP}$  indicates the number of false positives (FP);  $N^{b}$ (control, low score) =  $N^{b}_{TN}$  indicates number of true negatives (TN).

For each age and gender group, the absolute risk for AML in the bin is computed by  $r_{abs}^{b} = N_{case}^{b}/N^{b}$ . The absolute risk given a high score is estimated as  $r^{b}_{abs,high} = N^{b}_{TP}/(N^{b}_{FP} + N^{b}_{TP})$ . The relative risk in the bin is defined by  $\mathrm{rr}^b=r_{\mathrm{abs,high}}^b/r_{\mathrm{abs}}^b$  where the sensitivity level for the classifier threshold level is defined as  $\mathrm{sense}^b=N^b{}_{\mathrm{TP}}/N^b{}_{\mathrm{case}}$ .

$$rr = \frac{\frac{\frac{TP \times cases}{(TP + FN)}}{\frac{TP \times cases}{(TP + FN)} + \frac{FP \times controls}{(FP + TN)}}{\frac{cases}{cases + controls}}$$

Clonal growth rate calculation. Individual clones were defined by different mutations in different study participants. Per clone we calculated  $\alpha$  according to the following equation:

$$a = \log(V/V_0) / (T - T_0)$$

where T and  $T_0$  indicate the age of the individual at the two measurement time points. V and  $V_0$  correspond to the VAF at T and  $T_0$ , respectively.

Reporting summary. Further information on experimental design is available in the Nature Research Reporting Summary linked to this paper.

Code availability. Code for derivation of the prediction model is publically available on Github (https://github.com/gerstung-lab/preAML). Code for the analysis of error-corrected sequencing is available from the Shlush lab upon request.

Data availability. Targeted sequencing data for the discovery cohort are deposited as BAM files at the European Genome-phenome Archive (http://www.ebi.ac.uk/ ega/) under accession number EGAD00001003583. All other data are available from the corresponding authors upon reasonable request. Sequencing data for the validation cohort are deposited at the European Genome-phenome Archive with accession number EGAD00001003703.

Anaplastic meningioma is a rare and aggressive brain tumor characterised by intractable recurrences and dismal outcomes. Here, we present an integrated analysis of the whole genome, transcriptome and methylation profiles of primary and recurrent anaplastic meningioma. A key finding was the delineation of distinct molecular subgroups that were associated with diametrically opposed survival outcomes. Relative to lower grade meningiomas, anaplastic tumors harbored frequent driver mutations in SWI/ SNF complex genes, which were confined to the poor prognosis subgroup. Aggressive disease was further characterised by transcriptional evidence of increased PRC2 activity, stemness and epithelial-tomesenchymal transition. Our analyses discern biologically distinct variants of anaplastic meningioma with prognostic and therapeutic significance.

Meningiomas arise from arachnoidal cells of the meninges and are classified as grade I (80% of cases), grade II (10–20%) or grade III (1–3%). Grade III meningiomas comprise papillary, rhabdoid and anaplastic histological subtypes, with anaplastic tumors accounting for the vast majority of grade III diagnoses<sup>1,2</sup>. Nearly half of anaplastic meningiomas represent progression of a previously resected lower grade tumor, whereas the remainder arise *de novo*<sup>3,4</sup>. Recurrence rates are 5–20% and 20–40%, respectively, for grade I and II tumors<sup>2,5</sup>. By contrast, the majority of anaplastic meningioma patients suffer from inexorable recurrences with progressively diminishing benefit from repeated surgery and radiotherapy and 5-year overall survival of 30–60%<sup>4,6</sup>.

A recent study of 775 grade I and grade II meningiomas identified five molecular subgroups defined by driver mutation profile<sup>7</sup>. In keeping with previous smaller studies, mutually exclusive mutations in *NF2* and *TRAF7* were the most frequent driver events, followed by mutations affecting key mediators of PI3K and Hedgehog signal-ling<sup>7,8</sup>. Recurrent hotspot mutations were also identified in the catalytic unit of RNA polymerase II (*POLR2A*) in 6% of grade I tumors<sup>7</sup>. More recently, a study comparing benign versus *de novo* atypical (grade II) meningiomas found the latter to be significantly associated with *NF2* and *SMARCB1* mutations<sup>9</sup>. Atypical meningiomas were further defined by DNA and chromatin methylation patterns consistent with upregulated PRC2 activity, aberrant Homeobox domain methylation and transcriptional dysregulation of pathways involved in proliferation and differentiation<sup>9</sup>.

Despite the high mortality rate of anaplastic meningiomas, efforts to identify adjuvant treatment strategies have been hampered by a limited understanding of the distinctive molecular features of this aggressive subtype. A recent analysis of meningioma methylation profiles identified distinct subgroups within Grade III tumors predictive of survival outcomes, though the biology underpinning these differences and any therapeutic implications remain unknown<sup>10</sup>. Here, we present an analysis of the genomic, transcriptional and DNA methylation patterns defining anaplastic meningioma. Our results reveal molecular hallmarks of aggressive disease and suggest novel approaches to risk stratification and targeted therapy.

# Results

**Overview of the genomic landscape of primary and recurrent anaplastic meningioma.** We performed whole genome sequencing (WGS) on a discovery set of 19 anaplastic meningiomas resected at first presentation ('primary'). A subsequent validation cohort comprised 31 primary tumors characterised by targeted sequencing of 366 cancer genes. We integrated genomic findings with RNA sequencing and methylation array profiling in a subset of samples (Supplementary Table S1). Somatic copy number alterations and rearrangements were derived from whole genome sequencing reads, with RNA sequences providing corroborating evidence for gene fusions. Given the propensity of anaplastic meningioma to recur, we studied by whole genome sequencing 13 recurrences from 7 patients.

Excluding a hypermutated tumor (PD23359a, see Supplementary Discussion), the somatic point mutation burden of primary anaplastic meningioma was low with a median of 28 somatic coding mutations per tumor (range 11 to 71; mean sequencing coverage 66X) (Supplementary Fig. S1). Mutational signatures analysis of substitutions identified in whole genome sequences revealed the age-related, ubiquitous processes 1 and 5 as the predominant source of substitutions (Supplementary Fig. S2)<sup>11</sup>. The rearrangement landscape was also relatively quiet, with a median of 12 structural rearrangements (range 0–79) in the 18 primary tumor genomes (Supplementary Fig. S3, Table S3). Somatic retrotransposition events, a significant source of structural variants in over half of human cancers, were scarce (Supplementary Fig. S4, Table S4)<sup>12</sup>. Analysis of expressed gene fusions did not reveal any recurrent events involving putative cancer genes (Supplementary Table S5).

Recurrent large copy number changes were in keeping with known patterns in aggressive meningiomas, notably frequent deletions affecting chromosomes 1p, 6q, 14 and 22q (Fig. 1b, Supplementary Table S6)<sup>7,9,13</sup>.

**Driver genes do not delineate subgroups of anaplastic meningioma.** Over 80% of low grade meningiomas segregate into 5 distinct subgroups based on driver mutation profile<sup>7,9</sup>. In anaplastic meningioma, however, we found a more uniform driver landscape dominated by deleterious mutations in *NF2* (Fig. 1a). A key feature distinguishing anaplastic meningioma from its lower grade counterparts were driver events in genes of the SWI/SNF chromatin regulatory complex (Fig. 1a; Supplementary Fig. S7). The SWI/SNF (mSWI/SNF or BAF) complex is the most commonly mutated chromatin-regulatory complex in cancer<sup>14,15</sup>, and acts as a tumor suppressor in many cell types by antagonising the chromatin modifying PRC2<sup>16–18</sup>. The most frequently mutated SWI/SNF component was *ARID1A*, which harbored at least one deleterious somatic change in 12% of our cohort of 50 primary tumors (Supplementary Table S1). *ARID1A* has not been implicated as a driver in grade I or grade II meningiomas<sup>7,9</sup>. In total, 16% of anaplastic meningiomas contained a damaging SWI/SNF gene mutation. By contrast, SWI/SNF genes are mutated in <5% of benign and atypical meningiomas<sup>7,9</sup>.

In the combined cohort of 50 primary tumors, we found at least one driver mutation in *NF2* in 70%, similar to the prevalence reported in atypical meningiomas and more than twice that found in grade I tumors<sup>7,9</sup>. As observed in other cancer types, it is possible that non-mutational mechanisms may contribute to *NF2* loss of function in a proportion of anaplastic meningiomas<sup>19,20</sup>. We considered promoter hypermethylation as a source of additional *NF2* inactivation, but found no evidence of this (Supplementary Table S7). There was no significant difference in NF2 expression between *NF2* mutant and wild-type tumors (*p*-value 0.960; Supplementary Fig. S8), suggesting that a truncated dysfunctional protein may be expressed.

Other driver genes commonly implicated in low grade tumors were not mutated, or very infrequently (Fig. 1a). Furthermore, and consistent with the most recent reports<sup>7,9</sup>, we did not observe an increased frequency of *TERT* promoter mutations, previously associated with progressive or high grade tumors<sup>21</sup>. Notably<sup>13</sup>, meth-ylation analysis revealed *CDKN2A* and *PTEN* promoter hypermethylation in 17% and 11% of primary tumors, respectively (Fig. 1a). We did not find evidence of novel cancer genes in our cohort, applying established methods

**Figure 1.** The landscape of driver mutations and copy number alterations in anaplastic meningioma. (**a**) The landscape of somatic driver variants in primary anaplastic meningioma. Somatic mutation and promoter methylation data is shown for a discovery cohort of 18 primary tumors characterised by whole genome sequencing. Mutations in recurrently altered genes, established meningioma genes and SWI/SNF complex subunits are included. Samples are annotated for chromosome 22q LOH, prior radiotherapy exposure, and clinical presentation (*de novo* verus progression from a lower grade meningioma). The bar plot to the right indicates mutation frequency in a validation cohort of 31 primary tumors sequenced with a 366 cancer gene panel. Asterisks indicate genes not included in the targeted sequencing assay. (**b**) Aggregate copy number profile of primary anaplastic meningioma. For the 18 tumors characterized by whole genome sequencing, the median relative copy number change was calculated across the genome in 10 kilobase segments, adjusting for ploidy. The grey shaded area indicates the first and third quantile of copy number for each genomic segment. The solid red and blue lines represent the median relative copy number gain and loss, respectively, with zero indicating no copy number change. X-axis: Chromosomal position. Y-axis: median relative copy number change. Potential target genes are noted. AM, anaplastic meningioma; LOH, loss of heterozygosity; RT, radiotherapy.

to search for enrichment of non-synonymous mutations<sup>22</sup>. The full driver landscape of anaplastic meningioma, considering point mutations, structural variants with resulting copy number changes and promoter hypermethylation is presented in Supplementary Fig. S7.

The genomic landscape of recurrent tumors was largely static both with respect to driver mutations and structural variation. Driver mutations differed between primary and recurrent tumors for only two of eleven patients with serial resections available. For seven sets of recurrent tumors studied by whole genome sequencing, only two demonstrated any discrepancies in large copy number variants (PD23344 and PD23346; Supplementary Fig. S5). Similarly, matched primary and recurrent samples clustered closely together by PCA of transcriptome data, suggesting minimal phenotypic evolution (Supplementary Fig. S6).

**Differential gene expression defines anaplastic meningioma subgroups with prognostic and biological significance.** We performed messenger RNA (mRNA) sequencing of 31 anaplastic meningioma samples from a total of 28 patients (26 primary tumors and 5 recurrences). Gene expression variability within the cohort did not correlate with clinical parameters including prior radiotherapy, anatomical location or clinical presentation (*de novo* versus progressive tumor) (Supplementary Fig. S6). However, unsupervised hierarchical clustering demonstrated segregation of tumors into two main groups, hereafter referred to as C1 and C2 (Fig. 2a). These groups were recapitulated by principal component analysis (PCA) of normalised transcript counts (Fig. 2b), which delineated C1 as a well-demarcated cluster clearly defined by the first two principal components

3

**Figure 2.** Transcriptomic classification of anaplastic meningioma. (**a**) Unsupervised hierarchical clustering and (**b**) principal component analysis of anaplastic meningioma gene expression revealed two subgroups (denoted C1 and C2). (**c**) Dendrogram obtained by unsupervised clustering annotated with clinical and genomic features. (**d**) Volcano plot depicting genes differentially expressed between C1 versus C2 anaplastic meningioma samples. X-axis,  $\log_2$  fold change; y-axis,  $-\log_{10}$  adjusted *P*-value. Genes with an adjusted *P*-value < 0.01 and absolute  $\log_2$  fold change >2 are highlighted in red. (**e**,**f**) Box plots of (**e**) CXLC14 and (**f**) HOTAIR expression across 31 anaplastic meningomas classified into C1 and C2 subgroups, 100 primary breast tumors, and 219 cancer cell lines from 11 tumor types. Upper and lower box hinges correspond to first and third quartiles, horizontal line and whiskers indicate the median and 1.5-fold the interquartile range, respectively. Underlying violin plots show data distribution and are color-coded according to specimen source (blue, cell line; green, primary tumor). X-axis indicates tumor type and number of samples; y-axis shows  $\log_{10}$  TPM values. (**g**) Kaplan-Meier curves showing overall survival for 25 anaplastic meningioma patients in C1 and C2 subgroups for whom follow-up data was available. Dashes indicate timepoints at which subjects were censored at time of last follow-up. TPM, transcripts per kilobase million; AM, anaplastic meningioma; TNBC, triple negative breast carcinoma; wt, wild-type; mt, mutated; PC, principal component.

.....

(PC). Of note, all SWI/SNF mutations were confined to the poor prognosis (C1) subgroup (Fig. 2c). C1 constituted a more diffuse group on PCA, distinguished from C2 mainly along the first principal component. We next retrospectively sought follow-up survival data from the time of first surgery, which was available for 25 of the 28 patients included in the transcriptome analysis (12 patients in C1, 13 in C2; mean follow-up of 1,403 days from surgery). We observed a significantly worse overall survival outcome in C1 compared to C2 (P < 0.0001; hazard ratio 17.0, 95% CI 5.2–56.0) (Fig. 2g; Supplementary Table S8). The subgroups were well balanced with respect

to potential confounding features such as gender, age, radiotherapy, anatomical location and amount of residual tumor remaining after surgery (Supplementary Table S9).

Recent work has demonstrated that anaplastic meningiomas segregate into 2–3 prognostically significant subgroups on the basis of methylation profile<sup>10</sup>. Unsupervised hierarchical clustering using methylation data available for a subset of the cohort (n = 19) demonstrated segregation into two main groups largely overlapping the subgroups delineated on the basis of gene expression profile, though correlation with survival outcomes was less marked (Supplementary Fig. S8).

**Transcriptional programs segregating indolent and aggressive anaplastic meningioma.** Nineteen hundred genes underpinned the differentiation of anaplastic meningioma into subgroups C1 and C2, which could be reduced to only 6 transcripts selected on the basis of PCA coefficient and differential expression analysis (see Methods; Supplementary Tables S10 and S11, Fig. S9). Pathway enrichment analysis was most significant for evidence of epithelial-mesenchymal transition (EMT) in the C1 tumors, with concordant loss of E-cadherin (*CDH1*) and upregulation of *CXCL14*, both prognostic biomarkers in diverse other cancers (Supplementary Table S12, Fig. 2d-f)<sup>23-25</sup>. EMT, which involves reprogramming of adherent epithelial cells into migratory mesenchymal cells, is critical for embryogenesis and tissue plasticity, and can play an important role in malignant progression, metastasis and therapy resistance<sup>24,26</sup>. Interestingly, NF2 and the closely related cytoskeletal protein ezrin normally help maintain E-cadherin expression at adherence junctions, whereas *HOXB7* and *HOXB9*, both overexpressed in C1 tumors, suppress *CDH1* expression<sup>27-29</sup>. It is increasingly recognised that CXCL14 and other EMT mediators are often derived from cancer-associated fibroblasts (CAFs) and function in a paracrine manner<sup>25,30,31</sup>. It is hence possible that some of the gene expression patterns we observed may reflect differences in the tumor stromal compartment, itself an increasingly recognised therapeutic target<sup>30,32,33</sup>.

The C1 tumors were further characterised by upregulation of transcriptional programs associated with increased proliferation, PRC2 activity and stem cell phenotype (Supplementary Table S13). Hox genes constituted a notable proportion of the transcripts distinguishing the two anaplastic meningioma subgroups, largely underpinning the significance of pathways involved in tissue morphogenesis. Furthermore, differentially methylated genes were also significantly enriched for Hox genes, with pathway analysis results corroborating the main biological themes apparent from the transcriptome (Supplementary Tables S14 and S15). Given the transcriptional evidence of increased PRC2 activity in the C1 subgroup, is noteworthy that SWI/SNF gene mutations occurred exclusively in C1 tumors (P=0.016, Fisher's exact test).

**Comparison of the anaplastic and benign meningioma transcriptome.** Previous studies investigating the relationship between meningioma WHO grade and gene expression profiles have included few anaplastic tumors<sup>34,35</sup>. We therefore extended our analysis to include published RNA sequences from 19 benign grade I meningiomas. External data was processed using our in-house pipeline with additional measures taken to minimise batch effects (Methods, Supplementary Tables S16 and S17). Unsupervised hierarchical clustering and principal component analysis demonstrated clear tumor segregation by histological grade (Fig. 3a,b). In keeping with previous reports, the anaplastic tumors demonstrated marked upregulation of major growth factor receptor and kinase circuits implicated in meningioma pathogenesis, notably epidermal growth factor receptor (EGFR), insulin-like growth factor (IGFR), vascular endothelial growth factor receptor (VEGFR) and mTOR complex 1 (mTORC1) kinase complex<sup>36-41</sup>.

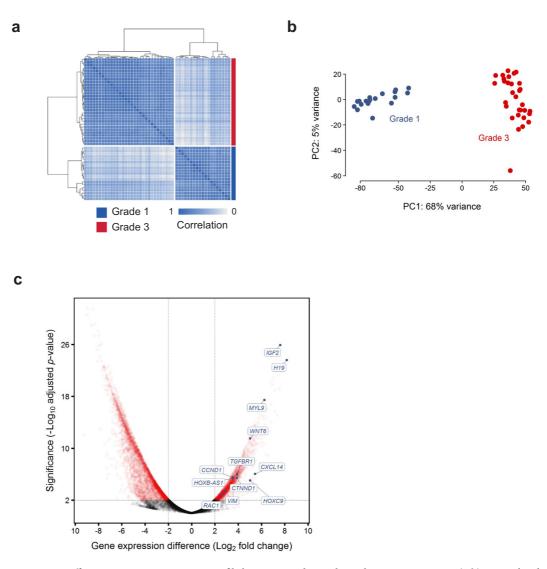

Consistent with there being a coherent biological trend across histological grades and anaplastic meningioma subgroups, we noted significant overlap between genes differentially expressed between grades and between C1 and C2 tumors (hypergeometric distribution  $P = 5.08 \times 10^{-9}$ ). In keeping with this finding, formal pathway analysis identified significant dysregulation of stemness, proliferation, EMT and PRC2 activity (Supplementary Tables S18 and S19). The most significantly dysregulated pathways also included TGF-beta, Wnt and integrin signalling, mediators of invasion and mesenchymal differentiation that are normally in part controlled by NF2 and other Hippo pathway members<sup>20,24,42</sup>. Yes-associated protein 1 (Yap1), a cornerstone of oncogenic Hippo signalling, is frequently overexpressed in cancer and synergises with Wnt signalling to induce EMT<sup>43,44</sup>. *YAP1* was upregulated in anaplastic tumors along with *MYL9*, a key downstream effector essential for Yap1-mediated stromal reprogramming (Fig. 3c)<sup>43</sup>.

## Discussion

Meningiomas constitute a common, yet diverse tumor type with few therapeutic options<sup>6,7,9,45</sup>. Efforts to improve clinical outcomes have been hampered by limited understanding of the molecular determinants of aggressive disease. Here, we explored genomic, epigenetic and transcriptional features of anaplastic meningioma, the most lethal meningioma subtype<sup>4</sup>.

Frequent somatic changes in SWI/SNF complex genes, predominantly *ARID1A*, constitute the main genomic distinction between anaplastic and lower grade meningiomas<sup>7,9</sup>. SWI/SNF inactivation is associated with aberrant PRC2 activation, stem cell-like phenotype and poor outcomes in diverse cancer types<sup>46–48</sup>.

Although anaplastic tumors resist comprehensive classification based on driver mutation patterns, transcriptional profiling revealed two biologically distinct subgroups with dramatically divergent survival outcomes. This finding is emblematic of the limitations of histopathological grading as a risk stratification system for meningioma<sup>2,4,10,45,49</sup>. All SWI/SNF mutations were confined to the poor prognosis (C1) subgroup, which was further characterised by transcriptional signatures of PRC2 target activation, stemness, proliferation and mesenchymal differentiation. These findings were in part underpinned by differential expression of Hox genes. Acquisition of invasive capacity and stem cell traits are frequently co-ordinately dysregulated in cancer, often through subversion of Hox gene programs integral to normal tissue morphogenesis<sup>50–52</sup>. Hox genes have a central role in orchestrating vertebrate development and act as highly context-dependent oncogenes and tumor suppressors in cancer<sup>51,53</sup>.

**Figure 3.** Differences in gene expression profile between grade I and anaplastic meningomas. (**a**,**b**) Normalised transcript counts from grade I and anaplastic meningioma samples clustered by (**a**) Pearson's correlation coefficient and (**b**) principal component analysis. (**c**) Volcano plot illustrating differences in gene expression between anaplastic versus grade I meningiomas with selected genes indicated. The horizontal axis shows the log<sub>2</sub> fold change and the vertical axis indicates the  $-\log_{10}$  adjusted *P*-value. Genes with an adjusted *P*-value < 0.01 and absolute log<sub>2</sub> fold change >2 are highlighted in red. PC, principal component.

.....

Several of the most starkly upregulated Hox genes in the C1 tumors consistently function as oncogenes across a range of solid and haematological malignancies, including HOTAIR, HOXB7, HOXA4, HOXA-AS2, HOXC11, and NKX2-2<sup>28,29,51,54-62</sup>. Like many other long non-coding RNAs (lncRNA), HOTAIR and HOXA-AS2 modulate gene expression primarily by interacting directly with chromatin remodelling complexes, exerting oncogenic activity by recruiting PRC2 to target genes<sup>54,56,61-65</sup>. *HOXA-AS2* has been shown to mediate transcriptional repression of the tumor suppressor gene CDKN2A (p16<sup>INK4A</sup>), deletion of which is associated with poor meningioma survival<sup>54,61,62,66,67</sup>. Given the antagonistic relationship between the SWI/SNF and PRC2 chromatin regulators, deleterious SWI/SNF mutations and overexpression of lncRNAs known to mediate PRC2 activity emerge as potentially convergent mechanisms underpinning the differences between C1 and C2 tumors<sup>68</sup>. Further endorsing a link between transcriptional subgroups and chromatin dysregulation, 15 of the differentially expressed transcripts delineating C1 and C2 subgroups (absolute log, fold change >2 and FDR < 0.01) are among the 50 genes most often associated with frequently bivalent chromatin segments (FBS) in cancer, including 11 transcripts from the HOXB cluster on chromosome 17<sup>69</sup>. This overlap was highly statistically significant (hypergeometric distribution  $P = 1.98 \times 10^{-11}$ ). Bivalent, or epigenetically 'poised', chromatin is characterised by finely balanced activating (H3K4me1/H3K4me3) and repressive (H3K27me3) histone marks and pre-loaded DNA polymerase II poised to transcribe in response to modest epigenetic changes<sup>70</sup>. Bivalent chromatin most often marks genes involved in developmental reprogramming, in particular Hox cluster genes and homeotic non-coding transcripts, and is a frequent target of aberrant chromatin modification in cancer<sup>65,69,71</sup>.

In the context of recent studies of lower grade meningiomas, our findings raise the possibility that the balance between PRC2 and SWI/SNF activity may have broader relevance to meningioma pathogenesis. Compared to grade I tumors, atypical meningiomas are more likely to harbor *SMARCB1* mutations and large deletions encompassing chromosomes 1q, 6q and 14q. Notably, these genomic regions encompass *ARID1A* and several other SWI/SNF subunit genes. Both *SMARCB1* mutations and the aforementioned copy number changes were associated with epigenetic evidence of increased PRC2 activity, differential Homeobox domain methylation, and upregulation of proliferation and stemness programs in atypical grade II meningiomas<sup>9</sup>.

The extent to which SWI/SNF depletion plays a role in meningioma development may be therapeutically relevant. Diverse SWI/SNF mutated cancers exhibit dependence on both catalytic and non-catalytic functions of EZH2, a core subunit of PRC2<sup>72-74</sup>. Several EZH2 inhibitors are in development with promising initial clinical results<sup>75</sup>. Other modulators of PRC2 activity, including *HOTAIR*, may also be relevant therapeutic targets<sup>76,77</sup>. Furthermore, growing recognition of the relationship between EMT and resistance to conventional and targeted anti-cancer agents has profound implications for rational integration of treatment approaches<sup>32,33</sup>. Notably, EGFR inhibition has yielded disappointing response rates in meningioma despite high EGFR expression<sup>37,78</sup>. A mesenchymal phenotype is strongly associated with resistance to EGFR inhibitors in lung and colorectal cancer<sup>32,33,79–81</sup>. Combining agents that abrogate EMT with other therapies is a promising strategy for addressing cell-autonomous and extrinsic determinants of disease progression and may warrant further investigation in meningioma<sup>32,33</sup>.

This study has revealed biologically and prognostically significant anaplastic meningioma subgroups and identified potentially actionable alternations in SWI/SNF genes, PRC2 activity and EMT regulatory networks. However, a substantially larger series of tumors, ideally nested in a prospective multicentre observational study, will be required to expand upon our main findings and explore mechanistic and therapeutic ramifications of meningioma diversity.

# Methods

**Sample selection.** DNA was extracted from 70 anaplastic meningiomas; 51 samples at first resection ('primary') and 19 from subsequent recurrences. Matched normal DNA was derived from peripheral blood lymphocytes. Written informed consent was obtained for sample collection and DNA sequencing from all patients in accordance with the Declaration of Helsinki and protocols approved by the NREC/Health Research Authority (REC reference 7/YH/0101) and Ethics Committee at University Hospital Carl Gustav Carus, Technische Universität Dresden, Germany (EK 323122008). Samples underwent independent specialist pathology review (V.P.C and K.A). DNA extracted from fresh-frozen material was submitted for whole genome sequencing whereas that derived from formalin-fixed paraffin-embedded (FFPE) material underwent deep targeted sequencing of 366 cancer genes.

One tumor sample PD23348 (and two subsequent recurrences) separated from the main study samples in a principal components analysis of transcriptomic data (Supplementary Fig. S10). Analysis of WGS and RNA sequencing data identified an expressed gene fusion, *NAB2-STAT6*. This fusion is pathognomonic of meningeal hemangiopericytoma, now classified as a separate entity, solitary fibrous tumors<sup>§2–84</sup>. We therefore excluded three samples from this tumor from further study. A second sample (PD23354a), diagnosed as an anaplastic meningioma with papillary features, was found to have a strong APOBEC mutational signature as well as an *EML4-ALK* gene fusion (exon 6 EML4, exon 19 ALK) (Supplementary Fig. S11)<sup>85</sup>. Therefore this sample was also removed as a likely metastasis from a primary lung adenocarcinoma. The hypermutator sample PD23359a underwent additional pathological review to confirm the diagnosis of anaplastic meningioma (K.A., Department of Histopathology, Cambridge University Hospital, Cambridge, UK).

RNA was extracted from fresh-frozen material from 34 primary and recurrent tumors, 3 of which were from PD23348 and were subsequently excluded from final analyses (Supplementary Table S1).

*Whole genome sequencing.* Short insert 500 bp genomic libraries were constructed, flowcells prepared and sequencing clusters generated according to Illumina library protocols<sup>86</sup>. 108 base/100 base (genomic), or 75 base (transcriptomic) paired-end sequencing were performed on Illumina X10 genome analyzers in accordance with the Illumina Genome Analyzer operating manual. The average sequence coverage was 65.8X for tumor samples and 33.8X for matched normal samples (Supplementary Table S1).

**Targeted genomic sequencing.** For targeted sequencing we used a custom cRNA bait set (Agilent) to enrich for all coding exons of 366 cancer genes (Supplementary Table S20). Short insert libraries (150 bp) were prepared and sequenced on the Illumina HiSeq 2000 using 75 base paired-end sequencing as per Illumina protocol. The average sequence coverage was 469X for the tumor samples.

**RNA sequencing and data processing.** For transcriptome sequencing, 350 bp poly-A selected RNA libraries were prepared on the Agilent Bravo platform using the Stranded mRNA library prep kit from KAPA Biosystems. Processing steps were unchanged from those specified in the KAPA manual except for use of an in-house indexing set. Reads were mapped to the GRCh37 reference genome using STAR (v2.5.0c)<sup>87</sup>. Mean sequence coverage was 128X. Read counts per gene, based on the union of all exons from all possible transcripts, were then extracted BAM files using HTseq (v0.6.1)<sup>88</sup>. Transcripts Per kilobase per Million reads (TPM) were generated using an in-house python script (https://github.com/TravisCG/SI\_scripts/blob/master/tpm.py)<sup>87,88</sup>. We downloaded archived RNA sequencing FASTQ files for 19 grade I meningioma samples representing the major mutational groups (*NF2*/chr22 loss, *POLR2A*, *KLF4/TRAF7*, *PI3K* mutant) (ArrayExpress: GSE85133)<sup>7</sup>. Reads were then processed using STAR and HTseq as described above. Cancer cell line (n = 252) and triple-negative breast cancer (n = 100) RNA sequencing data was generated in-house by the aforementioned sequencing and bioinformatic pipeline.

Expressed gene fusions were sought using an in-house pipeline incorporating three algorithms: TopHat-Fusion (v2.1.0), STAR-Fusion (v0.1.1) and deFuse (v0.7.0) (https://github.com/cancerit/cgpRna)<sup>87,89,90</sup>. Fusions identified by one or two algorithms or also detected in the matched normal sample were flagged as likely artefacts. Fusions were further annotated according to whether they involved a kinase or known oncogene and whether they occurred near known fragile sites or rearrangement break points<sup>91</sup> (Supplementary Table S5).

The C1 and C2 subgroups were defined by unsupervised hierarchical clustering using Poisson distance between samples<sup>92,93</sup>. Poisson distance was calculated using the PoissonDistance function implemented in the 'PoiClaClu' R package<sup>92</sup> and unsupervised hierarchical clustering performed with the stats::hclust() function using the 250 transcripts with the most variable expression across tumors. Silhouette information was computed using the cluster::silhouette() function. The highest mean silhouette score was consistently achieved with two clusters.

**Differential gene expression and pathway enrichment analysis.** The DESeq2 R package was used for all differential gene expression analyses<sup>94,95</sup>. DESeq2 uses shrinkage estimation of dispersion for the sample-specific count normalization and subsequently applies a linear regression method to identify differentially expressed genes (DEGs)<sup>94,95</sup>.

Preliminary comparison of anaplastic and externally-generated grade I meningioma data revealed evidence of laboratory batch effects, which we mitigated with two batch-correction methods: RUVg and PEER<sup>96,97</sup>. RUVg estimates the factor attributed to spurious variation using control genes that are assumed to have constant expression across samples<sup>98–100</sup>. We selected control genes (*RPL37A*, *EIF2B1*, *CASC3*, *IPO8*, *MRPL19*, *PGK1* and *POP4*) on the basis of previous studies of suitable control genes for transcript-based assays in meningioma<sup>101</sup>. PEER ('probabilistic estimation of expression residuals') is based on factor analysis methods that infer broad variance components in the measurements. PEER can find hidden factors that are orthogonal to the known covariates. We applied this feature of PEER to remove additional hidden effect biases. The final fitted linear regression model consists of the factor identified by RUVg method that represents the unwanted laboratory batch effect and 13 additional hidden factors found by PEER that are orthogonal to the estimated laboratory batch effect. Using this approach we were able to reduce the number of DEGs from more than 18000 to 8930, of which <4,000 are predicted to be protein-coding.

To identify biological pathways differentially expressed between meningioma grades and anaplastic meningioma subgroups we applied a functional class scoring algorithm using a collection of 461 published gene sets mapped to 10 canonical cancer hallmarks (Supplementary Table S21)<sup>50,102-106</sup>. We further corroborated these findings with a more general Gene Ontology (GO) pathway analysis<sup>107</sup>.

**Identification of 6 transcripts recapitulating anaplastic meningioma clusters.** Mapped RNA sequencing reads were normalised using the regularised logarithm (rlog) function implemented by the DESeq2 package<sup>94,95</sup>. PCA was performed using the top 500 most variably expressed transcripts and the R stats::prcomp function<sup>108</sup>. Given that primary component 1 (PC1) was the vector most clearly distinguishing the closely clustered C2 subgroup from the more diffusely clustered C1 (Fig. 3a), we extracted the top 50 transcripts with the highest absolute PC1 coefficients. We then identified the subset that overlapped with the most significantly differentially expressed genes (absolute log<sub>2</sub> fold change >4 and adjust *p*-value < 0.0001) between i) the C1 and C2 anaplastic meningioma subgroups and ii) the C1 anaplastic meningiomas and the 19 grade I tumors (Supplementary Tables S10 and S17). Iteratively reducing the number of PC1 components identified the minimum number of transcripts that recapitulated segregation of C1 and C2 tumors upon unsupervised hierarchical clustering and PCA (Supplementary Table S11, Fig. S9).

**Processing of genomic sequencing data.** Genomic reads were aligned to the reference human genome (GRCh37) using the Burrows-Wheeler Aligner, BWA (v0.5.9)<sup>109</sup>. CaVEMan (Cancer Variants Through Expectation Maximization: http://cancerit.github.io/CaVEMan/) was used for calling somatic substitutions. Small insertions and deletions (indels) in tumor and normal reads were called using a modified Pindel version 2.0. (http://cancerit.github.io/cgpPindel/) on the NCBI37 genome build<sup>110,111</sup>. Annotation was according to ENSEMBL version 58. Structural variants were called using a bespoke algorithm, BRASS (BReakpoint AnalySiS) (https://github.com/cancerit/BRASS) as previously described<sup>112</sup>.

The ascatNGS algorithm was used to estimate tumor purity and ploidy and to construct copy number profiles from whole genome data<sup>113</sup>.

**Identification of cancer genes based on the impact of coding mutations.** To identify recurrently mutated driver genes, we applied an established dN/dS method that considers the mutation spectrum, the sequence of each gene, the impact of coding substitutions (synonymous, missense, nonsense, splice site) and the variation of the mutation rate across genes<sup>22</sup>.

**Identification of driver mutations in known cancer genes.** Non-synonymous coding variants detected by Caveman and Pindel algorithms were flagged as putative driver mutations according to set criteria and further curated following manual inspection in the Jbrowse genome browser<sup>114</sup>. Variants were screened against lists of somatic mutations identified by a recent study of 11,119 human tumors encompassing 41 cancer types and also against a database of validated somatic drivers identified in cancer sequencing studies at the Wellcome Trust Sanger Institute (Supplementary Tables S22 and S23)<sup>115</sup>.

Copy number data was analysed for homozygous deletions encompassing tumor suppressor genes and for oncogene amplifications exceeding 5 or 9 copies for diploid and tetraploid genomes, respectively. Only focal (<1 Mb) copy number variants meeting these criteria were considered potential drivers. Additional truncating events (disruptive rearrangement break points, nonsense point mutations, essential splice site mutations and

frameshift indels) in established tumor suppressors were also flagged as potential drivers. Only rearrangements with breakpoints able to be reassembled at base pair resolution are included in this dataset.

**TraFiC pipeline for retrotransposon integration detection.** For the identification of putative solo-L1 and L1-transduction integration sites, we used the TraFiC (Transposome Finder in Cancer) algorithm<sup>12</sup>. TraFiC uses paired-end sequencing data for the detection of somatic insertions of transposable elements (TEs) and exogenous viruses. The identification of somatic TEs (solo-L1, Alu, SINE, and ERV) is performed in three steps: (i) selection of candidate reads, (ii) transposable element masking, (iii) clustering and prediction of TE integration sites and (iv) filtering of germline events<sup>12</sup>.

**Methylation arrays and analysis.** We performed quantitative methylation analysis of 850,000 CpG sites in 25 anaplastic meningiomas. Bisulfite-converted DNA (bs-DNA) was hybridized on the Ilumina Infinium HumanMethylationEPIC BeadChip array following the manufacturer's instructions. All patient DNA samples were assessed for integrity, quantity and purity by electrophoresis in a 1.3% agarose gel, picogreen quantification and Nanodrop measurements. Bisulfite conversion of 500 ng of genomic DNA was done using the EZ DNA Methylation Kit (Zymo Research), following the manufacturer's instructions. Resulting raw intensity data (IDATs) were normalized using the Illumina normalization method developed under the minfi R package (v1.19.10). Normalized intensities were then used to calculate DNA methylation levels (beta values). We then excluded from the analysis the positions with background signal levels in methylated and unmethylated channels (p > 0.01). Finally we removed probes with one or more single nucleotide polymorphisms (SNPs) with a minor allele frequency (MAF) >1% in the first 10 bp of the interrogated CpG, as well as the probes related to X and Y chromosomes. From the filtered positions, we selected only CpG sites present both in promoter regions (TSS, 5'UTR and 1st exon) and CpG islands (UCSC database, genome version hg19).

For the supervised analysis of the probes, CpG sites were selected by applying an ANOVA test to identify statistically significant CpG positions (FDR adjusted p-value < 0.01) that were differentially methylated among the compared groups ( $\Delta\beta$  > 0.2). Selected CpG sites were later clustered based on the Manhattan distances aggregated by ward's linkage. Finally, the genes corresponding to the selected CpGs were used to perform a Gene Set Enrichment Analysis (GSEA) with curated gene sets in the Molecular Signatures Database<sup>116</sup>. The gene sets used were: H: hallmark gene sets, BP: GO biological process, CC: GO cellular component, MF: GO molecular function and C3: motif gene sets (http://software.broadinstitute.org/gsea/msigdb/collections.jsp). The gene clusters resulting from the hypergeometric test with a FDR adjusted p-value < 0.05 were finally considered. We observed high levels of methylation for *CREBBP* in the majority of tumor samples, however, similar patterns were manifest in normal tissue controls, hence *CREBBP* hypermethyation does not appear to be a feature of oncogenesis in these samples.

For principal component analysis, we used the R function prcomp to calculate the Singular Value Decomposition of the beta value matrix after removing the CpGs without methylation information. We plotted the first two principal components which contain most variation by using the ggbiplot R package (http://github. com/vqv/ggbiplot). For each group we plotted a normal data ellipse with size defined as a normal probability equal to 0.68. Unsupervised hierarchical clustering was performed with the stats::hclust() function using the 75 probes with the highest variance in methylation beta values.

**Mutational signature analysis.** Mutational signature extraction was performed using the nonnegative matrix factorization (NNMF) algorithm<sup>11</sup>. Briefly, the algorithm identifies a minimal set of mutational signatures that optimally explains the proportions of mutation types found across a given mutational catalogue and then estimates the contribution of each identified signature to the mutation spectra of each sample.

**Patient survival analysis.** The Kaplan-Meier method was used to analyze survival outcomes by the log-rank Mantel-Cox test, with hazard ratio and two-sided 95% confidence intervals calculated using the Mantel\_Haenszel test (GraphPad Prism, ver 7.02). Overall survival data from time of first surgery for each anaplastic meningioma within gene-expression defined subgroups C1 and C2 was collected and used to plot a Kaplan-Meier survival curve.

# Supplementary Discussion

A hypermutator anaplastic meningioma with a haploid genome. One primary anaplastic meningioma resected from an 85-year old female (PD23359a) had a hypermutator phenotype, with 27,332 point mutations and LOH across nearly its entire genome (Supplementary Fig. S12, Table S24). Independent pathological review confirmed the original diagnosis of anaplastic meningioma, and transcriptome analysis demonstrated that this tumor clustered appropriately with the rest of the cohort (Fig. 3a,b). The majority of the mutations were substitutions, 72% of which were C > T transitions. We identified two deleterious mutations in DNA damage repair mediators: a *TP53* p.R248Q missense mutation and a homozygous truncating variant in the mismatch repair gene *MSH6* (p.L1330Vfs\*9). Despite the latter finding, mutational signatures analysis was dominated by signature 1, with no evidence of signatures typically associated with defects in homologous recombination, mismatch repair or *POLE* activity (signatures 3, 6, 10, 15, 20 or 26). The copy number profile is most consistent with this tumor having first undergone haploidization of its genome, with the exception of chromosome 7, 19 and 20, followed by whole genome duplication (Supplementary Fig. S12). Of note, several important oncogenes are located on chromosome 7, including *EGFR*, *MET* and *BRAF*. Widespread LOH has been described in a significant proportion of oncocytic follicular thyroid cancers where preservation of chromosome 7 heterozygosity has also been observed<sup>117</sup>.

# **Data Availability**

All sequencing data that support the findings of this study have been deposited in the European Genome-Phenome Archive and are accessible through the accession numbers EGAS00001000377, EGAS00001000828, EGAS00001000859, EGAS00001001155 and EGAS00001001873. All other relevant data are available from the corresponding author on request.

Soft tissue tumors of infancy encompass an overlapping spectrum of diseases that pose unique diagnostic and clinical challenges. We studied genomes and transcriptomes of cryptogenic congenital mesoblastic nephroma (CMN), and extended our findings to five anatomically or histologically related soft tissue tumors: infantile fibrosarcoma (IFS), nephroblastomatosis, Wilms tumor, malignant rhabdoid tumor, and clear cell sarcoma of the kidney. A key finding is recurrent mutation of *EGFR* in CMN by internal tandem duplication of the kinase domain, thus delineating CMN from other childhood renal tumors. Furthermore, we identify *BRAF* intragenic rearrangements in CMN and IFS. Collectively these findings reveal novel diagnostic markers and therapeutic strategies and highlight a prominent role of isolated intragenic rearrangements as drivers of infant tumors.

1

any childhood tumors show a predilection for specific developmental stages. Tumors that predominantly occur in infancy include congenital mesoblastic nephroma (CMN), which accounts for 4% of all childhood renal malignancies and the majority of those diagnosed in children under 6 months of age<sup>1,2</sup>. CMN is classified histologically into classical, cellular, and mixed subtypes based primarily on degree of cellularity and mitotic activity<sup>3</sup>. The cellular variant is characterized by a sarcoma-like diffuse hypercellular morphology, whereas classical CMN is composed of less proliferative spindle cells<sup>3</sup>. Cellular CMN is driven by rearrangements involving the tropomyosin receptor kinase (TRK) gene NTRK3, most commonly a t(12;15)(p13;q25) reciprocal translocation with the ETV6 transcription factor<sup>4,5</sup>. Less frequent somatic aberrations include trisomies of chromosomes 8, 11, 17, and 20<sup>6,7</sup> and rarer TRK fusions, involving *NTRK1*, *NTRK2*, or *NTRK3*<sup>8</sup>. By contrast, the genetic changes underpinning the classical variant, accounting for >30% of cases, are unknown<sup>9</sup>. Cellular CMN shares its genetic and morphological hallmarks with infantile fibrosarcoma (IFS), a spindle cell tumor typically arising in the soft tissues of the extremities or abdomen<sup>5,9,10</sup>

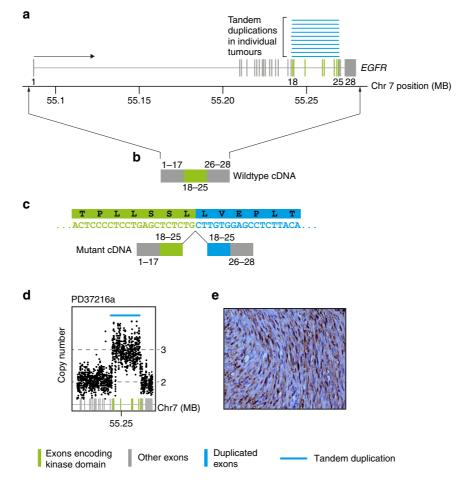

Standard treatment for CMN and IFS is complete surgical resection<sup>9–11</sup>. In the case of IFS, local control frequently requires cytotoxic chemotherapy<sup>10,11</sup>. The role for up-front chemotherapy in CMN is less clear<sup>9</sup>. Recently, a phase I/II clinical trial of a

selective TRK inhibitor, larotrectinib, reported high response rates in diverse tumor types harboring TRK gene fusions, including IFS and other soft tissue tumors of infancy<sup>12</sup>. Morbidity and infrequent death result from tumor recurrence or from treatment-related complications<sup>9–11</sup>.

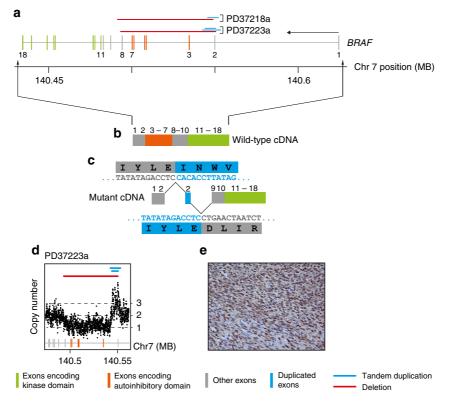

Here, we investigated the genetic basis of CMN and IFS lacking the canonical *NTRK3-ETV6* fusion gene. We identify oncogenic rearrangements in MAPK signaling genes across all cases interrogated by unbiased sequencing, notably therapeutically tractable intragenic rearrangements in *EGFR* and *BRAF*.

# Results

**Overview of the genomic landscape of CMN**. To identify the genetic basis of cryptogenic CMN, we first applied whole genome and transcriptome sequencing to a discovery cohort of ten classical CMN lacking an *NTRK3* fusion (Supplementary Data 1). Somatic variants were identified by comparing tumor and matched peripheral blood sequences (see Methods). The genomic landscape was universally quiet, with a low burden of point mutations (median of 45 substitutions and 9 insertions or deletions per genome; Supplementary Data 2). The predominant mutational signatures, as defined by the trinucleotide context of substitutions, were the ubiquitous signatures 1 and  $5^{13}$ 

**Fig. 1** *EGFR* internal tandem duplication. **a** The genomic footprint of *EGFR* is depicted with exons represented by gray and green vertical lines. Green exons encode the kinase domain. Blue lines superiorly show the tandem duplications found in the discovery cohort of ten congenital mesoblastic nephroma of classical histology. **b** Schematic of the wild-type transcript. **c** Schematic of the fusion transcript annotated with cDNA sequence of rearrangements (sense orientation) and protein translation. **d** Intragenic copy number of *EGFR* showing focal amplification over the kinase domain (*x*-axis: genomic coordinate; *y*-axis: copy number derived from coverage). **e** Representative phospo-ERK immunohistochemistry

**Fig. 2** Internal *BRAF* deletion. **a** The genomic footprint of *BRAF* is depicted with exons represented by gray, green, and orange vertical lines. Green and orange exons encode the kinase domain and conserved region 1, respectively. Horizontal lines above exons demarcate rearrangements (blue: tandem duplication; red: deletion). **b** Outline of wild-type transcript. **c** Outline of fusion transcript with cDNA sequence of rearrangements (sense orientation) with translation. **d** Intragenic copy number of *BRAF* (*x*-axis: genomic coordinate; *y*-axis: copy number derived from coverage). **e** Representative phospho-ERK immunohistochemistry

(Supplementary Fig. 1). Copy number changes and structural rearrangements were likewise scarce (Supplementary Fig. 2).

Internal tandem duplication of the EGFR kinase domain in CMN. Annotating all cases for potential oncogenic variants revealed a single intragenic, in-frame internal tandem duplication (ITD) of the EGFR kinase domain in all ten tumors (Table 1; Fig. 1; Supplementary Data 3). The breakpoints clustered in a narrow genomic window around the kinase domain of EGFR encoded in exons 18-25 (Fig. 1a). This rearrangement is rarely observed in several other tumor types including in glioma and in lung adenocarcinoma, and confers sensitivity to a targeted EGFR inhibitor, afatinib<sup>14</sup>. We validated all rearrangements by genomic copy number analysis and reconstruction of cDNA reads spanning the breakpoint junction (Fig. 1; see Methods). Of note, the same mutant cDNA junction sequence was found in every case, irrespective of the genomic location of breakpoints. A search for additional known or novel driver variants revealed no further plausible candidates in any of the EGFR-mutant tumors. We next extended this investigation to seven non-classical CMN lacking an NTRK3 fusion, including four mixed cellularity cases and three cellular tumors (Table 1; Supplementary Data 1). Two of the four mixed cellularity tumors surveyed also harbored an EGFR-ITD. Of note, for one child with EGFR-ITD-positive mixed cellularity CMN (PD37214), both primary tumor and recurrence were studied, with no additional driver events apparent at relapse.

**BRAF rearrangements in CMN and IFS.** A further striking finding was the discovery of mutations in the *BRAF* oncogene in 2/3 cellular histology CMNs. *BRAF* fusions have been implicated in a minority of IFS but not in CMN<sup>15</sup>. In both cases the *BRAF* 

rearrangement involved a compound deletion of conserved region 1 (CR1) and tandem duplication of exon 2 (Fig. 2; Table 1; Supplementary Data 3). CR1 encompasses the negative regulatory Rasbinding domain (RBD), loss of which is predicted to generate a constitutively active form of BRAF<sup>16,17</sup>. Mutated tumors displayed intense staining of phosphorylated ERK by immunohistochemistry, consistent with activated signaling downstream of BRAF (Figs. 1e and 2e). A further tumor harbored the *KIAA1549-BRAF* fusion, a molecular hallmark of a childhood brain tumor, pilocytic astrocytoma<sup>18,19</sup>. This fusion likewise results in loss of the N-terminal portion of the BRAF protein containing the RBD<sup>17,18</sup>.

**Other TRK fusions in CMN**. The remaining two cases of CMN interrogated by whole genome and transcriptome sequencing were accounted for by gene fusions involving *NTRK1*, an alternate kinase of the TRK family of protein kinases: *TPR-NTRK1* and *LMNA-NTRK1*. Both of these fusions have been observed in IFS and rarely in adult cancers, but not, to our knowledge, in CMN<sup>20-23</sup> (Table 1). Hence, every cryptogenic CMN interrogated by whole-genome sequencing contained an oncogenic rearrangement in *BRAF*, *EGFR*, or *NTRK1*, all of which encode kinases involved in MAPK signaling and are amenable to inhibition with existing drugs<sup>9,12,14,17,24</sup>.

*EGFR-ITD* distinguishes CMN from other childhood renal tumors. To validate and extend our findings, we screened IFS and a range of childhood renal tumors for *EGFR*-ITD, *BRAF*-ID, and *ETV6*-*NTRK3* using PCR. Tumor types included additional cases of CMN (n = 63), IFS (n = 26), Wilms tumor (n = 208), clear cell sarcoma of the kidney without *BCOR* rearrangements (n = 20), malignant rhabdoid tumor (n = 3), and nephroblastomatosis

<sup>a</sup>Negative for BCOR rearrangement

(n = 12; Table 1; Supplementary Data 1). *EGFR*-ITD was most prevalent in classical and mixed cellularity CMN, though was also found in cellular CMN (2/17 cases). The frequency of *EGFR* rearrangement in classical tumors was lower in the validation cohort (20/35 cases) than in the initial discovery cohort (10/10 cases). None of the IFS cases, nor other childhood kidney tumors, harbored *EGFR*-ITD. However, we encountered three cases of IFS with intragenic *BRAF* deletions. Remarkably, in two cases *BRAF*-ID co-occurred with *NTRK3* fusions, the disease-defining mutation of IFS. We were unable to accurately estimate relative allele frequencies by nested PCR (see Methods). Hence, it is possible that both fusions co-exist within the same clone or represent independent clones that evolved in parallel within the same tumor.

# Discussion

In this exploration of infant tumors we identify ITD of the *EGFR* kinase domain that delineates a genetic subgroup of CMN transcending histological subtypes. Additionally, we report a novel rearrangement of *BRAF* present in both cellular CMN and IFS. These mutations represent diagnostic markers that can be readily integrated into routine clinical practice. Furthermore, EGFR and BRAF emerge as therapeutic targets, which may be exploited in certain clinical situations, e.g., large surgically intractable tumors, disease recurrence or metastases.

It is noteworthy that an oncogenic mutation was identified in every tumor that we studied by whole-genome sequencing. Of these, 78% harbored either EGFR-ITD or BRAF-ID, while the remaining 22% presented with non-canonical mutations involving BRAF, NTRK1, or NTRK3. This suggests that less recurrent rearrangement variants, albeit implicated in the same signaling circuity, may elude detection by targeted diagnostic assays. Moreover, our results indicate that a subset of tumors harbor multiple drivers with important implications for targeted therapy efforts. The finding of co-mutation of NTRK3 and BRAF in IFS raises the possibility of intrinsic resistance of some tumors to TRK inhibition, regardless of whether these mutations occur in the same clone or in independent competing clones. This finding is pertinent to clinical trials of TRK inhibitors in CMN and IFS<sup>12</sup>. In this vein a structurally similar BRAF fusion transcript, albeit without duplication of exon 2, has recently been implicated as a mechanism of resistance to certain BRAF/MEK inhibitors<sup>16,17</sup>. These considerations underscore the need for adequate genomic profiling in order to match patients to the most appropriate basket studies and to enable meaningful interpretation of

4

treatment responses. Therefore, we would advocate extending the diagnostic work-up of refractory or relapsed CMN and IFS to whole genome sequencing, particularly in the context of clinical trials.

Biologically our findings draw further parallels between CMN and IFS. We identify BRAF and NTRK1 as additional cancer genes operative in both malignancies, substantiating the view that these diagnoses represent variants on the same disease spectrum converging on aberrant RAS-RAF-MEK-ERK signaling<sup>5,8,9</sup>. Furthermore, in the wider context of the childhood cancer genome, our findings add to the growing body of studies that identify short distance intragenic rearrangements as a dominant source of oncogenic mutations in otherwise quiet genomes. We note the parallel between CMN, clear cell sarcoma of the kidney and low-grade glioma that are in large part driven by ITDs often involving kinase domains, mostly as isolated driver events<sup>18,25-29</sup>. Furthermore, even in acute myeloid leukemia, where FLT3-ITD is a recurrent driver event in adult disease, childhood AML demonstrates a distinct structural variant profile enriched for focal chromosomal gains and losses<sup>30</sup>. We can only speculate on the biological significance of this parallel which may allude to specific mutational mechanisms operative during discrete stages of human development.

# Methods

Patient samples. All tissue samples were obtained after gaining written informed consent for tumor banking and future research from the patient (or their guardian) in accordance with the Declaration of Helsinki and appropriate national and local ethical review processes. German tissue samples were obtained from the following studies: SIOP93-01/GPOH and SIOP2001/GPOH (Ethikkommission der Ärztekammer des Saarlandes reference numbers 23.4.93/Ls and 136/01), the PTT2.0 study (Medical Faculty Heidelberg ethics reference number S-546/2016), the CWS trials CWS-96 and CWS-2002P (Universitätsklinikum Tübingen Medizinische Fakultät ethics approval, reference numbers 105/95 and 51/2003) and the SoTiSaR registry (ethics approval reference 158/2009B02). UK patients were enrolled under ethics approval from National Research Ethics Service Committee East of England, Cambridge Central (reference 16/EE/0394). Use of UK archival material was approved by the National Research Ethics Service Committee London Brent (reference 16/LD/0960). Additional tissue was obtained from the UK Children's Cancer and Leukaemia Group tissue bank.

Sequencing. Tumor DNA and RNA were extracted from fresh frozen tissue that had been reviewed by reference pathologists. Normal tissue DNA was derived from blood samples. Whole genome sequencing was performed by 150-bp paired-end sequencing on the Illumina HiSeq X platform. We followed the Illumina no-PCR library protocol to construct short insert libraries, prepare flowcells, and generate clusters. Coverage was at least 30×. Messenger RNA was enriched by polyA-

DOI: 10.1038/s41467-018-04650-6 www.nature.com/naturecommunications

selection and sequenced on an Illumina HiSeq 2000 (paired end, 75-bp read length). DNA and RNA sequencing reads were aligned to the GRCh 37d5 reference genome using the Burrows–Wheeler transform  $(BWA-MEM)^{31}$  and STAR  $(2.0.42)^{32}$ , respectively.

Variant detection. The Cancer Genome Project (Wellcome Trust Sanger Institute) variant calling pipeline was used to call somatic mutation and includes the fol-lowing algorithms: CaVEMan (1.11.0)<sup>33</sup> for substitutions, an in-house version of Pindel (2.2.2; github.com/cancerit/cgpPindel)<sup>34</sup> for indels, BRASS (5.3.3; github. com/cancerit/BRASS) for rearrangements, and ASCAT NGS (4.0.0) for copy number aberrations<sup>35</sup>. RNA sequences were analyzed with an in-house pipeline (github.com/cancerit/cgpRna/wiki) which uses HTSeq<sup>36</sup> for gene feature counts, and a combination of TopHat-Fusion (v2.1.0)<sup>37</sup>, STAR-fusion (v0.1.1)<sup>32</sup> and DeFuse (v0.7.0)<sup>38</sup> to detect expressed gene fusions. In addition to filters inherent to the CaVEMan algorithm, we used the following post-processing filtering criteria for substitutions: a minimum of two reads in each direction reporting the mutant allele, at least tenfold coverage at the mutant allele locus, minimum variant allele fraction 5%; no insertion or deletion called within a read length (150 bp) of the putative substitution, no soft-clipped reads reporting the mutant allele, and a median BWA alignment score of the reads reporting the mutant allele ≥140. The following variants were flagged for additional inspection for potential artifacts, germline contamination or index-jumping event: any mutant allele reported within 150 bp of another variant, any mutant allele with a population allele frequency >1 in 1000 according to any of five large polymorphism databases (ExAC, 1000 Genomes Project, ESP6500, CG46, Kaviar), variant reported in more than 10% of the tumor samples and mutant allele reported in >1% of the matched normal reads. For indels, the inbuilt filters of the Pindel algorithm, as implemented in our pipeline, were used. In addition, recurrent indels occurring in >2 samples were flagged for additional inspection.

Mutational signatures were derived using principal component analysis and non-negative matrix factorization as implemented in the SomaticSignatures R package<sup>39</sup>.

**Variant validation**. The Cancer Genome Project (Wellcome Trust Sanger Institute) variant calling pipeline has been continually validated and bench-marked<sup>40,41</sup>. We confirmed variant calling quality through manual visual inspection of raw sequencing read for 8% of all variants called. All rearrangements reported were validated by reconstruction at base pair resolution and by cDNA reads spanning the breakpoint junction.

**Analysis of mutations in cancer genes**. We considered variants as potential drivers if they presented in established cancer genes<sup>42</sup>. Tumor suppressor coding variants were considered if they were annotated as functionally deleterious by an in-house version of VAGrENT (http://cancerit.github.io/VAGrENT/)<sup>43</sup> or were disruptive rearrangement breakpoints or focal (<1 Mb) homozygous deletions. Mutations in oncogenes were considered driver events if they were located at previously reported canonical hot spots (point mutations) or amplified the intact gene. Amplifications also had to be focal (<1 Mb) and increase the copy number of oncogenes to a minimum of five copies for a diploid genome. To search for driver variants in novel cancer genes or in non-coding regions, we employed previously developed statistical methods that identify significant enrichment of mutations, taking into account various confounders such as overall mutation burden and local variation in the mutability of the genomic region<sup>44</sup>.

**Targeted mutation screening.** RNA from frozen tumors (1 µg) or corresponding to approximately 5 cm<sup>2</sup> of 10 µm FFPE sections was reverse transcribed using oligo-dT or random hexamer primers (RevertAid first strand cDNA synthesis kit, ThermoFisher). PCR screening was performed using primer combinations that allow amplification of candidate alterations as well as additional control fragments from the unaffected allele to assess cDNA quality. Amplified fragments were sequenced by Sanger sequencing (GATC, Konstanz, Germany) using primers detailed in Supplementary Table 1.

**Immunohistochemistry**. Immunohistochemical staining for phospho-ERK1/2 (Cell Signaling Technology, clone D13.14.4E) was performed according to standard protocol (dilution 1:800, pre-treatment with target retrieval TR6.1, Dako). Results were scored in a semi-quantitative fashion (negative, weak, moderate, strong).

**Code availability**. The algorithms used to analyze sequencing data are available at http://cancerit.github.io/.

**Data availability**. All data supporting the findings of this study are available within the article and its supplementary files or from the corresponding author on reasonable request. Sequencing data have been deposited at the European Genome-Phenome Archive (http://www.ebi.ac.uk/ega/) that is hosted by the European Bioinformatics Institute (accession numbers EGAS00001002534 and EGAS00001002171).

# **Recurrent histone mutations in T-cell acute lymphoblastic leukaemia**

Mutations affecting key modifiable histone type 3 (H3; Table SI) residues are frequent oncogenic events in certain solid tumours (Feinberg *et al*, 2016), and have also recently been implicated in a subset of acute myeloid leukaemia (AML) (Lehnertz *et al*, 2017). Here, we systematically reviewed the somatic mutations in >20 000 cancer specimens to identify tumours harbouring H3 mutations. In a subset of T-cell acute lymphoblastic leukaemia (T-ALL) we identified non-methionine mutations of the key modifiable H3 residues, lysine (K) 27 and 36.

The starting point of our investigation was a search for H3 hotspot mutations in 1020 human cancer cell lines (Table SII). In two cell lines, both derived from T-ALL, we found lysineto-arginine mutations at H3K27 and H3K36 (Table I). One of the cell lines, LOUCY, is derived from a NOTCH1 wild-type adult T-ALL (Ben-Bassat et al, 1990). The second, CML-T1, was derived from the T-lymphoblastic blast crisis of chronic myeloid leukaemia (Kuriyama et al, 1989). Ten further T-ALL cell lines lacked coding H3 mutations (Table SIII). In solid tumours, H3K27 and H3K36 are typically mutated to methionine (Fig 1) (Feinberg et al, 2016). However, recent functional studies of H3 lysine-to-isoleucine mutations in AML demonstrate that the latter also dramatically alter global H3 methylation and acetylation patterns (Lehnertz et al, 2017). Therefore, we speculated that lysine-to-non-methionine mutations may also be drivers of a subset of T-ALL.

We next searched for canonical H3 mutations in a published targeted sequencing study of 633 epigenetic regulator genes in >1000 childhood tumours encompassing 21 cancer subtypes (Huether *et al*, 2014). Amongst 91 T-ALL specimens, there were two cases with canonical H3 mutations: *H3F3A* p.K27R and *H3F3A* p.K36R (Table I). Both mutations were clonal, with a variant allele fraction (VAF) of 38% and 55%, respectively. Among the 37 tumours with H3K mutations, lysine-to-arginine mutations were restricted to T-ALL (P = 0.001502; Fisher's exact test).

We then extended our screen for H3 mutations to 18 704 tumours, encompassing >60 cancer types other than T-ALL (Tables SIV and SV). This dataset comprised 8764 internally sequenced specimens and 9940 TCGA samples re-analysed using an in-house variant calling pipeline as previously described (Martincorena *et al*, 2017). We identified only one neomorphic H3 mutation in an acute leukaemia specimen: a previously reported *HIST1H3D* p.K27M mutation in an adult AML case (TCGA-AB2927-03) (Lehnertz *et al*, 2017).

Finally, we examined an additional T-ALL cohort by capillary sequencing of recurrently mutated modifiable residues K27, G34, and K36 across four frequently mutated H3 genes (Tables SVI and SVII). The cohort comprised 38 T-ALL cases described in detail previously (Maser *et al*, 2007). One specimen from a 30-year-old patient harboured a *H3F3A* p.K27N mutation (Figure S1). Interestingly, a *H3F3A* p.K27N mutation and a *H3F3A* p.K27T variant were previously identified in a T-ALL RNA sequencing study (n = 31) (Atak *et al*, 2013). Collectively, our findings indicate that H3K27 and H3K36 mutations are recurrent in T-ALL, a result we were able to reproduce across multiple different cohorts encompassing adult and paediatric cases.

This finding is congruent with the fact that mutations in *SETD2* and *EZH2*, methyltransferases that catalyse trimethylation (me3) of H3K36 and H3K27, respectively, are frequent T-ALL drivers (Belver & Ferrando, 2016). Disruptive *SETD2* alterations occur in 7.8% of early T cell precursor acute lymphoblastic leukaemia (ETP-ALL), an aggressive subtype with stem cell-like features (Belver & Ferrando, 2016). Interestingly, both T-ALL specimens with H3K36R mutations originated from ETP-ALL (Table I). Notably, mutually exclusive *SETD2* and H3K36/H3K34 mutations are reported in paediatric high grade glioma, where both result in reduced H3K36me3 mediated by *SETD2* (Feinberg *et al*, 2016). It is unclear whether a similar co-mutation pattern exists in T-ALL, as H3 genes have not been included in targeted sequencing panels used by the largest T-ALL genomic studies (Belver & Ferrando, 2016).

The role of H3K27 modifications in T-ALL pathogenesis is complex (Belver & Ferrando, 2016). It is plausible that mutations affecting this residue could impact the activity of several histone modifiers with established roles in T-ALL pathogenesis. Loss-of-function mutations in EZH2 or other core components of Polycomb repressive complex 2 (PRC2) are found in 42% of ETP-ALL and 25% of T-ALL overall (Belver & Ferrando, 2016). Impaired PRC2 catalytic activity in T-ALL is associated with reduced H3K27me3, stemness and poor prognosis (Belver & Ferrando, 2016). H3F3A p.K27M mutations appear to act predominantly by blocking H3K27 di- and trimethylation and increasing H3K27 acetylation (Feinberg et al, 2016). Recent work demonstrates that H3K27I mutations in AML are associated with similar changes in H3 modification patterns (Lehnertz et al, 2017), suggesting that other non-methionine mutations at modifiable H3 residues may influence the activity of PRC2 and

Table I. Type 3 histone mutations in T cell leukaemia.

Out of 141 T cell leukaemia specimens screened (12 cell lines and 129 primary samples), 5 (3.5%) harboured a missense mutation at a modifiable lysine residues K27 or K36. CML, chronic myeloid leukaemia; ETP-ALL, early T cell precursor acute lymphoblastic leukaemia; T-ALL, T cell acute lymphoblastic leukaemia.

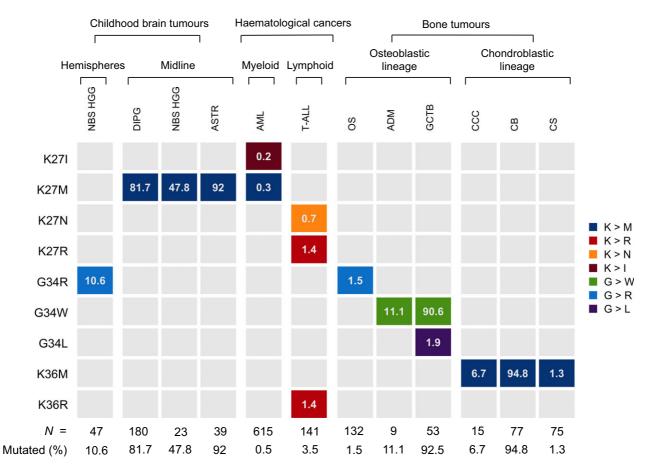

Fig 1. Prevalence and amino acid specificity of type 3 histone mutations in different cancer types. Columns indicate cancer types and rows show key histone type 3 regulatory residues. Tiles are coloured according to amino acid substitution. The percentage of each tumour type affected by the given class of histone mutation is indicated within the tiles and the overall prevalence of histone mutations is summarised at the bottom of each column. NBS HGG, non-brain stem high grade glioma; DIPG, diffuse intrinsic pontine glioma; ASTR, astrocytoma; AML, acute myeloid leukaemia; T-ALL, T cell acute lymphoblastic leukaemia; OS, osteosarcoma; ADM, adamantinoma; GCTB, giant cell tumour of bone; CCC, clear cell chondrosarcoma; CB, chondroblastoma; CS, chondrosarcoma.

other histone modifying enzymes. The lysine-specific demethylases *JMJD3* and *UTX* are further important regulators of H3K27me3 distribution in T-ALL (Belver & Ferrando, 2016), and it is conceivable that these enzymes may also be affected by H3K27 or H3K36 mutations.

A feature of H3 mutations in solid cancers is their exquisite tumour type specificity (Fig 1) (Feinberg *et al*, 2016). In this context, it is notable that 5/5 H3 mutations in T-ALL identified by this survey are lysine-to-non-methionine mutations, and 4/5 are lysine-to-arginine mutations. Out of the >20 000 tumour specimens screened for H3 variants, only two other samples harboured H3 lysine-to-arginine mutations, both at low VAF and in tumours with relatively high coding mutation burdens (TCGA-BT-A20Q-01 and TCGA- AN-A0FW-01). Hence, it is possible that lysine-to-arginine mutations confer particular selective advantage in the context of T cell leukaemogenesis.

In summary, ~3% of T-ALL harbour non-methionine variants in H3 genes at key modifiable lysine residues. Given the role of dysregulated H3K27/H3K36 modification in T-ALL pathogenesis and the established prognostic significance of mutations in lysine-specific histone modifiers (Belver & Ferrando, 2016), this finding warrants further investigation of the prevalence, clinical and functional significance of H3 mutations in T-ALL. In light of the recent discovery of oncogenic H3K37 mutations in AML (Lehnertz *et al*, 2017), our findings suggest a broader role for histone mutations in acute leukaemias and clearly justify incorporation of H3 genes into haematological cancer sequencing panels.

Hairy cell leukemia (HCL) is a chronic, incurable B cell malignancy that presents with splenomegaly, bone marrow infiltration, and cytopenias [1]. Long remissions are typically achieved with purine analogs such as cladribine, but most cases will relapse and require further therapy. The discovery of the *BRAF* V600E mutation in almost all cases of HCL [2] has led to the widespread adoption of the BRAF inhibitor vemurafenib for treatment of patients relapsing after cladribine [3–5]. Impressive responses are reported; however, relapse is inevitable [5, 6] and hematologists are now faced with a growing number of patients with vemurafenib-resistant HCL. The optimal management of these patients remains unclear.

The molecular basis of vemurafenib resistance has been extensively investigated in recent years in patients with *BRAF* mutant solid organ malignancies such as melanoma and colorectal cancer [7]. Resistance to vemurafenib in melanoma frequently results from reactivation of ERK

pathway signaling by a variety of genetic mechanisms that include activating mutations of *NRAS* or *KRAS*, amplification of mutant *BRAF*, aberrant splicing of *BRAF*, and activating mutation of *MAP2K1*, which encodes the MEK1 protein [7, 8]. ERK-independent mechanisms are less frequent and include activation of PI3K signaling [7]. The predominance of genetic mechanisms converging on ERK reactivation has led to the successful use of dual MEK/ BRAF inhibition in melanoma [9]. In colorectal cancer however, different mechanisms apply; here primary resistance usually results from reduced feedback inhibition upon upstream receptor tyrosine kinase activity leading to restoration of ERK activity [10]. In this scenario, combined BRAF and MEK inhibition has not proved effective [11].

In contrast to our comprehensive understanding in solid organ cancer, very little is known about the mechanistic basis of vemurafenib resistance in HCL. Given the diversity of resistance mechanisms established in other cancers, it is unclear which, if any, of these might predominate in HCL. Two acquired subclonal, activating *KRAS* mutations were previously reported in a single patient with vemurafenib resistance [5]. Deletions of *NF1* and *NF2* have been proposed as an alternative mechanism in another case of primary resistance [12]. The use of MEK inhibition has been suggested as a logical therapeutic strategy in patients who have reactivated ERK signaling. However, the use of MEK inhibition has never previously been reported in a patient with HCL and at present there is no consensus on the optimal management of patients relapsing on vemurafenib.

A 74-year-old patient with HCL had been treated at our institution with splenectomy, cladribine, and pentostatin. We previously reported his initial response to vemurafenib at a dose of 240 mg twice daily [4]. This dose was lower than used in the initial phase II trial [5], but has since been shown in several reports to be an effective dosing strategy for HCL [3, 13, 14]. Vemurafenib was initially stopped after 58 days; however, this was associated with rapid return of marrow infiltration and thrombocytopenia. Vemurafenib was restarted at the same dose and cytopenias rapidly

further platelet transfusion. A second trial of two doses of rituximab produced a minimal improvement of platelet count to  $30 \times 10^9$ /l. The patient became systemically unwell with B symptoms. Bone marrow trephine biopsy confirmed 99% infiltration with HCL.

To elucidate the mechanism of his resistance we performed whole-genome and deep-targeted sequencing of 292 genes (Supplementary Table 1) of DNA from purified tumor cells collected prior to starting vemurafenib and again at relapse. Samples were used with informed written patient consent in accordance with the Declaration of Helsinki and appropriate institutional ethical approvals. Sequencing studies revealed the presence of the known BRAF V600E mutation and chromosome 7q deletion. Remarkably, we also identified seven distinct activating mutations in KRAS and two mutations in MAP2K1 (encoding MEK1) (Fig. 1b and Supplementary Table 2). These were detectable at relapse but were not detectable prior to vemurafenib exposure. Allele frequencies were consistent with the parallel, convergent evolution of multiple clones. Deep-targeted amplicon sequencing at multiple time points showed how KRAS mutations developed early, initially with codon 146 mutations, followed by emergence of the more classical activating mutations of codons 12 and 61 [15]. MAP2K1 mutations appeared later with MAP2K1 p.K57T expanding to become the dominant clone (Fig. 2c and Supplementary Table 2). The convergent nature of these mutations strongly implicated reactivation of MEK-ERK signaling as the likely mechanism of resistance. Indeed, immunohistochemistry confirmed strong pERK activity in all tumor cells (Fig. 2a). We looked for other mechanisms of resistance reported in melanoma. Specifically, we found no genetic or protein evidence of either increased pAKT activity or altered BRAF splicing (Supplementary Figure 1A & B).

We concluded that reactivation of MEK/ERK activity was the most likely driver of relapse and hypothesized that MEK inhibition might be a successful therapeutic strategy. Expression of the KRAS and MAP2K1 mutants in a lymphoid cell line showed that while each mutation was able to activate ERK in the presence of vemurafenib, all mutations remained sensitive to MEK inhibition (Fig. 1d). Exposure of the patient's purified tumor cells to vemurafenib ex vivo failed to completely suppress ERK activity and did not induce apoptosis. In contrast, ERK activity was completely suppressed and apoptosis induced by exposure to a MEK inhibitor (Supplementary Figure 1C and Fig. 1c).

Based on our in vitro experiments, we treated the patient with the MEK inhibitor cobimetinib, initially at 20 mg daily combined with vemurafenib 240 mg twice daily. Remarkably, B symptoms resolved within 1 week, followed by rapid platelet count recovery. A bone marrow biopsy at 4 months showed complete suppression of ERK activity (Fig. 2a). However, HCL marrow infiltration persisted, and therefore cobimetinib dose was increased to 60 mg daily (taken 21 out of 28 days). The dose was well tolerated and was associated with further resolution of cytopenias, a substantial reduction in bone marrow cellularity and HCL infiltration, ongoing suppression of ERK activity and restoration of normal hematopoiesis (Fig. 2a, b). Ongoing treatment was also associated with suppression of mutant allele frequencies for *BRAF*, *KRAS*, and *MAP2K1* mutations (Fig. 2c). At 12 months, the patient remains well and asymptomatic with continued combination therapy.

The finding of nine activating mutations, all converging upon the activation of RAS/RAF/MEK/ERK signaling, underscores the centrality of this pathway in HCL and its reactivation as a potent mechanism of resistance to vemurafenib in this disease. This report provides a detailed analysis of the molecular basis for acquired vemurafenib resistance in HCL. It is the first reported use of a MEK inhibitor to treat vemurafenib-resistant HCL. It proposes a new therapeutic option for such patients and provides impetus for testing in a formal trial setting.

# Clonal haematopoiesis is not prevalent in survivors of childhood cancer

Clonal haematopoiesis driven by leukaemia-associated somatic mutations is a common feature of ageing (Link & Walter, 2016). This phenomenon, termed clonal haematopoiesis of indeterminate potential (CHIP), is associated with an increased risk of haematological malignancies and all-cause mortality (Link & Walter, 2016). Recent empirical evidence and computational models suggest that mutation acquisition may not be the major rate-limiting factor in the emergence of CHIP (Altrock et al, 2015; McKerrell et al, 2015; Link & Walter, 2016; Young et al, 2016). Instead, clonal expansion of mutant haematopoietic stem cells (HSCs) probably reflects the interaction between the effects of driver mutations and selection pressures prevailing in the bone marrow microenvironment (Link & Walter, 2016). Notably, cytotoxic therapies have been shown to favour expansion of pre-malignant haematopoietic clones (Link & Walter, 2016). Furthermore, both adult and paediatric cancer patients treated with intensive chemoradiotherapy display an earlier onset of ageing-associated morbidities and an elevated risk of therapy-related myeloid neoplasms (t-MN) and other secondary malignancies (Rowland & Bellizzi, 2014). A recent study in adult cancer patients found that CHIP was more prevalent than in the general population and was strongly associated with t-MN and overall mortality (Gibson et al, 2017). Although CHIP is extremely rare in healthy young individuals, its prevalence and prognostic significance in paediatric cancer patients has not been studied. We therefore performed targeted deep sequencing of peripheral blood DNA from 84 childhood cancer survivors to search for subclonal mutations common in t-MN and adult clonal haematopoiesis. No individuals with somatic variants at these loci were identified. Whilst our findings could be explained by a rarity of driver mutations, the fact that human HSCs accrue somatic variants from the first decade of life (Welch et al, 2012) proposes the alternative possibility that such mutations may not confer clonal advantage in the young.

We obtained peripheral blood DNA samples from patients enrolled on long-term follow-up after treatment for a paediatric malignancy and from three age-matched controls with no cancer history. Written informed consent was obtained for sample collection and DNA sequencing from all patients or their guardian in accordance with the Declaration of Helsinki and protocols approved by the relevant institutional ethics committees (approval numbers 09REG2015, 1-09/12/ 2015). The median age at cancer diagnosis was 4-5 years, and the commonest malignancies were acute lymphoblastic leukaemia (n = 21), neuroblastoma (n = 17) and non-Hodgkin lymphoma (n = 10). Nineteen patients had received a HSC transplant (8 allogeneic and 11 autologous). The median interval between completion of cancer treatment and blood sampling was 6 years (range 2–25). Patient characteristics are summarized in Table SI.

We performed targeted next generation sequencing (NGS) using multiplex polymerase chain reaction to amplify 32 regions of 14 genes frequently mutated in CHIP or t-MN (Table I) (McKerrell et al, 2015; Link & Walter, 2016; Gibson et al, 2017). For this we extended a previously validated assay that detected clonal haemopoiesis in 2.6% of unselected adults (McKerrell et al, 2015), to include all coding exons of TP53 and PPM1D, genes implicated in t-MN pathogenesis (Rowland & Bellizzi, 2014; Link & Walter, 2016; Gibson et al, 2017). Primer design and sequencing was performed as described previously (McKerrell et al, 2015); see Table SII for primer sequences. Reads were aligned to human genome build GRCh37 using the Burrows-Wheeler Aligner (Li & Durbin, 2010) and analysed for somatic single nucleotide variants. Allele counts were generated using an in-house script (https://github.com/cancerit/alleleCount), considering only loci with ≥1000 reads and minimum base and mapping quality of 25 and 35, respectively. Somatic mutations with

variant allele frequency (VAF)  $\geq$ 0.008 (McKerrell *et al*, 2015) were sought and examined visually and by interrogation with the Shearwater algorithm (https://github.com/mg14/dee pSNV) (Gerstung *et al*, 2014).

The median sequencing depth across regions of interest was  $5.3 \times 10^3$ . No somatic mutations with VAF  $\ge 0.008$ were observed in any of our patients or controls, demonstrating that CHIP driven by mutations at these loci is not prevalent in young individuals who have received cytotoxic treatment. By contrast, Gibson et al (2017) identified postchemotherapy CHIP (VAF > 0.02) in 29.9% of 401 adult lymphoma patients. Notably, mutations in PPM1D, a regulator of TP53, were the commonest CHIP drivers (Gibson et al, 2017). Similarly, several smaller studies have demonstrated clonal expansion in older patients undergoing chemoradiotherapy for other cancers (Link & Walter, 2016). An investigation of haematopoietic clonal dynamics in 15 adult acute myeloid leukaemia patients found that, after induction chemotherapy, five had marked expansion of clones unrelated to their leukaemia (Link & Walter, 2016). Most clones carried canonical leukaemia mutations and continued to expand years after remission (Link & Walter, 2016). In a study exploring the clonal origins of t-MN, TP53-mutated clones expanded dramatically after cytotoxic treatment, whereas the same mutations demonstrated very modest clonal advantage in healthy individuals (Link & Walter, 2016). In light of the above, our findings have two plausible explanations: (i) that somatic driver mutations are very uncommon in young individuals even after exposure to chemotherapy or (ii) that accrual of such mutations is insufficient to trigger clonal expansion in this age group. The latter is supported by findings that oncogenic mutations begin accumulating early in life (Welch et al, 2012) and that cancer-associated mutations are less able to drive clonal expansion in young compared to old stem cells (Zhu et al, 2016). The fact that bona-fide driver mutations do not always lead to haematopoietic clonal expansion, even after several years, was highlighted by Young et al (2016), using ultra-sensitive sequencing. Therefore our results should not be taken to reflect absence of potentially oncogenic HSC mutations in young cancer survivors. Rather, it is possible that even canonical leukaemogenic mutations may not commonly drive clonal outgrowth in children and young adults despite exposure to extreme haematopoietic stress, implicating age-related changes in HSCs and/or their microenvironment as key determinants of relative fitness. More sensitive DNA sequencing methods may enable detection of very rare cells harbouring known CHIP drivers mutations in similar patient cohorts, which would lend support to this hypothesis. Studies of larger numbers of paediatric cancer survivors are needed to identify rare individuals with CHIP after chemoradiotherapy, whose particular characteristics may offer insights into factors facilitating clonal outgrowth of mutated HSCs. Furthermore, in view of the shifting patterns of mutations

driving CHIP in different adult age groups (McKerrell *et al*, 2015), selective pressures particular to a less mature bone marrow environment may confer clonal advantage on a distinct spectrum of somatic variants in the very young. Although a much broader screening approach is required to identify such mutations, the potential role for CHIP as a biomarker for patient risk-stratification (Gibson *et al*, 2017) may render this a worthwhile endeavour.
